* The data on cat number 436 are not included in Table 5 since data on the second hour specimen was not available

controls This has been done in tables 4 and 5 and the various factors tested for significance by the computation of "Student's" t-ratios and the corresponding 'P' or probability values ⁵⁴

The significance of the differences in the means for each factor at each interval of

time can be readily seen by looking at the 'P' means in each table. 'P' values of 0.01 to 0.05 are generally considered statistically significant. Values in the neighborhood of .10 may have questionable significance. When values much above this level are encountered there is considered to be no detectable significant difference between the compared factors.

The control group was administered no adrenal cortical extract. The figures for the means are in every instance presented as a percentage of the mean of the standard of reference.

Analysis and Discussion of Data

It can be clearly seen from tables 4 and 5 that under the conditions of these experiments no significant effect attributable to the injection of large doses of adrenal cortical hormone was demonstrable. Whether lymph flow, the number of lymphocytes per cubic millimeter of lymph, or the total number of lymphocytes per hour

are compared, there is no significant difference between the untreated animals, the normal animals administered adrenal cortical extract, or the adrenalectomized animals administered adrenal cortical hormone. Moreover, this is true whether the

*1 Control Group

σ = Standard Deviation for each mean

†3 Adrenalectomized + Cortex Group $M_1 - M_2$ = Difference in the two means i.e. Mean of Group 1 minus Mean of group 2

NOTE The first hour after treatment represents the third hour after cannulation in each group. The first two hours were employed as a baseline standard of reference. The control group was administered no adrenal cortical extract. The figures for the means are in every instance presented as a percentage of the mean of the standard of reference.

first two hours after cannulation or the second hour only is used as a baseline standard of reference. If the 'P' or probability values for all factors and for both standards of reference are examined, only 8 out of the entire group are found to be below 10. In 3 of these 8, values for the treated groups were "significantly" higher than the values for the control group although the time interval after injection was

such that the opposite might have been expected. In 5 of the 8, values were higher in the control than in the treated group. In only one instance were "P" values of 10 or below obtained with *both* standards of reference. These are found in the fourth hour after injection (sixth hour after cannulation) when comparison is made of the mean absolute lymphocytes per cubic millimeter of the control group and the normal group receiving adrenal cortical extract. In this instance, the values for the treated group were above those for the control group and thus the reverse of what would be expected according to the hormonal hypothesis. In all other instances where apparently significant "P" values were obtained for one standard of reference they were not for the other. In short, the data in these experiments give no clue to any significant effect of adrenal cortical extract on the numbers of lymphocytes or rate of flow of thoracic duct lymph. No trend of any sort is detectable after hormone injection.

Although several factors were analysed, the total lymphocytes delivered by the thoracic duct per hour should, on theoretical grounds at least, have been the most important. Regardless of the numbers of lymphocytes per unit of lymph or the rate of lymph flow, as far as maintaining the numbers of blood lymphocytes is concerned, the pertinent factor is the total number delivered to the blood. Examination of the data shows no suggestion of a trend in this important factor.

Data are available for six hours after the injections of hormone (eight hours after cannulation) in the treated groups. This interval of observation was considered sufficiently long since in all species studied on which there are previous reports maximum depression of blood lymphocytes after the administration of adrenal cortical extract was found to occur within three to six hours after injection. The small amount of data available on thoracic duct lymphocyte levels after the administration of adrenal cortical hormone also suggested depression well within this time interval.

It should be noted that rate of flow of thoracic duct lymph in cannulated animals tends to diminish as time goes on. In measuring the effect of any factor on rate of flow a control group is therefore highly important. This diminution in flow is not unexpected since all the factors incident to the procedure including the loss of lymph from the body would predispose to reduction in the rate of lymph flow.

In addition to the experiments analysed in the tables, six additional experiments of the same type have been performed. In five of these, normal animals were injected with adrenal cortical extract after obtaining baseline determinations as a standard of reference, in one experiment, an adrenalectomized animal was similarly treated. These have not been included in the detailed analysis of the data because adrenal cortical extract was not administered until more than two hours after cannulation. Thus, hour by hour comparison with the major body of the experiments could not validly be made. However, examination of the data in these experiments likewise shows no demonstrable trend following the injection of hormone. They are essentially comparable to the data reported in detail in the tables.

It was of interest to note that significant changes were not apparent even in the adrenalectomized group of animals. These had presumably been deprived for a period of a few days of any effect of the sugar hormone of the adrenal cortex on

their lymphoid structures. It was thought that any effect of adrenal cortical extract on thoracic duct lymphocytes would be readily manifest in such a group.

Conclusions

Under the conditions of these experiments on the cat and with the dosage and preparations of adrenal cortical hormone employed, it has been impossible to demonstrate significant hormonal effects on the numbers of lymphocytes or rate of flow of thoracic duct lymph.

B STUDIES ON THE BLOOD COUNTS OF CATS BEFORE AND AFTER ADRENALECTOMY

Presentation of Data

The following data indicate the total and differential leukocyte counts in fifteen cats before and after bilateral adrenalectomy. The studies reported were made by one of us (J. S. L.)¹² a few years prior to the present investigation. In every instance repeated determinations of the numbers and differential formula of the white blood cells in the peripheral blood were made prior to adrenalectomy. Blood was obtained from the ear vein, and determinations were made only with Bureau of Standards equipment. In two instances, one set of observations only was made. In all other cases three or more white blood cell studies were made during the control period and in eight of the fifteen animals five or more control observations were obtained. In practically all instances the blood studies were made at daily intervals during the postoperative period. All animals lived at least seven days after the removal of both adrenal glands and the average survival period was ten days. No animals received hormonal maintenance therapy after adrenalectomy. All animals developed the

typical picture of adrenal insufficiency prior to death and on postmortem examination no adrenal tissue was found in any case. Operations were aseptically performed and at autopsy trivial skin or wound infections were found in only 2 animals (numbers one and eight) and osteomyelitis of the tail in one animal (number five). The values given in the table are the *averages* of the observations made before and after adrenalectomy. The data are presented in table 6.

Discussion

It can readily be seen that the average lymphocyte count per cubic millimeter went down after adrenalectomy in eight animals and rose in seven. The average absolute lymphocyte count was slightly less after operation than before it. A neutrophilic leukocytosis was observed after adrenalectomy.

The results obtained in this laboratory do not agree with the findings of Corey and Britton.⁶ The latter workers observed extreme reductions in total leukocyte and neutrophil counts in the adrenalectomized cat. In their animals these alterations resulted in an increase in the per cent of lymphocytes, but the striking blood changes involved the neutrophil. It was suggested that the extreme reductions in total leukocyte and neutrophil counts might be due to *neutrophilogenic* failure resulting from adrenalectomy. The reason for the discrepancy between the findings in this laboratory and those of Corey and Britton are not entirely clear. It is possible that animals used in the earlier work developed infectious feline agranulocytosis⁴¹ during the postoperative period. This highly infectious disease of cats, a condition not known at the time of Corey and Britton's work, would well explain some of the findings.

Conclusions

In fifteen cats the average total lymphocyte count after bilateral adrenalectomy was not significantly different from the average count prior to operation. A neutrophilic leukocytosis was observed to follow the operative procedure.

PART II THE PRESENT STATUS OF THE ROLE OF THE ADRENAL CORTEX IN THE REGULATION OF LYMPHOID TISSUE STRUCTURE AND FUNCTION AND OF THE NUMBERS OF CIRCULATING BLOOD LYMPHOCYTES

A INTRODUCTION

The concept of hormonal control of lymphoid tissue structure and function and of the numbers of blood lymphocytes is an intriguing one. Its most recent and comprehensive evaluation has been made by Dougherty and White.²¹ It is the purpose of this review to set forth in a detailed manner the experimental findings which form the foundation for the concept and to attempt to evaluate critically the merits of data both favoring and disfavoring it.

For purposes of convenience the studies relating to hormonal regulation of lymphoid tissue and lymphocytes can be roughly separated into four main groups: (1) Morphologic alterations in lymphoid tissue due to variations in adrenal cortical hormone activity; (2) Effect of varying amounts of available adrenal cortical hormone on the numbers of thoracic duct lymphocytes and rate of flow of thoracic duct

lymph (3) Changes in the numbers of circulating peripheral blood lymphocytes with variations in the available adrenal cortical hormone (4) Alterations in factors thought related to lymphoid tissue and lymphocyte function occurring with varying adrenal cortical hormonal activity The variations in available adrenal cortical hormone have been studied experimentally in many different ways In some instances adrenal cortical extract or purified steroids have been employed to augment the naturally occurring adrenal cortical secretion In other studies the adrenal activity of the experimental subject has been enhanced by the administration of adrenocorticotrophic hormone In still other investigations the subject has been stressed or "alarmed" with the design of calling forth increased adrenal cortical activity as a response to injurious stimuli Conversely, the effects of diminished or absent adrenal cortical hormone have been sought in the experimentally adrenalectomized animal or in human subjects with Addison's disease Most of the evidence has been obtained from animal work However, some evidence has been derived from the effects of hormonal preparations on normal man and from studies on patients with disturbed adrenal cortical metabolism The studies will be discussed under the four groupings mentioned before with the realization that some investigations may overlap into more than one group

B EVIDENCE OF GROSS AND HISTOLOGIC ALTERATIONS IN LYMPHOID TISSUE ATTRIBUTABLE TO THE ACTION OF ADRENAL CORTICAL HORMONE

Review of Medical Literature

According to Grollman,³⁰ changes in lymphatic tissue repeatedly have been noted in Addison's disease Clinically these are manifest by enlargement of lymphatic nodules at the base of the tongue, of tonsils, and of other palpable lymphoid tissue Star⁶⁵ is credited with having first noted that the thymus in a 17 year old girl dying from Addison's disease was persistent and as large as that of a child twelve months old In addition, in animals dying of chronic adrenal insufficiency there may be, according to Grollman, striking hypertrophy and regeneration of the thymus In young animals subjected to adrenalectomy, the growth of the thymus is stimulated, in older animals, the involuted thymus regenerates This summarization by Grollman is amply supported by the literature both antedating and succeeding his monograph

Joffe,³⁷ in 1924, using a moderately large group of Wistar rats, clearly demonstrated thymic enlargement in all rats surviving double suprarenalectomy in good condition for from three to five weeks This occurred even though the animal lost weight after the operation Histologically and grossly, the thymus in these animals was uniformly demonstrated to resemble the growing thymus of much younger animals and to differ markedly from the glands of nonoperated controls of the same age The same author³⁸ reviewed this subject three years later, including the evidence that the suprarenal glands are hypoplastic in patients dying with so-called status thymicolymphaticus Simpson and co-workers,⁶⁴ in 1934, found the thymuses of adrenalectomized rats to average 58 per cent greater than those of control animals allowed the same food intake Reinhardt and Holmes³⁵ likewise found that the thymus and lymph nodes of rats were much heavier in adrenalectomized animals maintained forty-five days on 1 per cent sodium chloride than were those of normal controls or controls receiving sodium chloride but not adrenalectomized

Conversely, the thymus and lymphatic structures have repeatedly been observed to involute following the administration of adrenal cortical hormone or of adrenocorticotrophic hormone to animals with intact adrenals Thus, Moon⁴⁸ reported the observation of complete atrophy of the thymus in spayed rats given adrenocorticotrophic hormone This was in marked contrast to the findings in untreated spayed controls Very little objective data was reported Ingle and Mason⁴⁶ demonstrated loss of weight of thymic glands in rats in which cortin was implanted subcutaneously in the form of solid pellets Ingle and co-workers³⁵ administered cortin and purified adrenal cortical preparations by various routes to rats The animals were then killed at intervals and the weight of various organs compared with normal values

The thymus gland showed marked progressive atrophy in those rats treated with cortin in doses of 5 to 10 cc daily. Each cc represented about 75 Gm. of whole adrenal gland. In the same year (1938), Evans et al.²⁴ reported marked loss of weight of the thymus in rats after administration of adrenocorticotrophic hormone. Ingle²⁵ demonstrated substantial involution of the thymus in the intact rat after administration of large amounts of cortin and similar atrophy in hypophysectomized rats when additional cortin was supplied animals in which the adrenal cortices had been maintained at normal size by regulated amounts of a renocorticotrophic hormone. Wells and Kendall,⁶⁶ in 1940, found the average thymus weight of 6 rats fed large doses of a highly potent, noncrystalline fraction of adrenal cortex was 27 per cent less than that of 20 controls, while the average thymus weight of 6 rats receiving corticosterone was 63 per cent less than that of controls. Neither desoxycorticosterone or its acetate, administered in drinking water or subcutaneously, produced involution of the thymus in these studies. Ingle³⁴ the same year reported that 2 mg. of 17 hydroxy-11-dehydrocorticosterone administered daily for seven days to 5 adrenalectomized rats lowered the average weight of the thymus to 24.6 mg. from 447.9 mg. in control animals. In a similar study employing the same dose of 11 desoxycorticosterone, there was no significant regression of the thymus in five rats. However, thymic regression of mild degree occurred when the daily dose of desoxycorticosterone was raised to 10 mg. Crede and Moon⁸ demonstrated that adrenocorticotrophic hormone produced thymic atrophy in 21 to 23 day old rats when given in three daily injections, and that the degree of atrophy observed was related up to a point to the dose of adrenocorticotrophic hormone. This was also true in control rats but could not be demonstrated in adrenalectomized rats. Noble and Collip⁶² were likewise able to confirm the constant presence of thymic atrophy after the administration of corticotrophins to normal and hypophysectomized rats. Dougherty and White,¹¹ in 1943, showed quite clearly that pituitary adrenocorticotrophic hormone injected in CBA strain mice produced a decrease in weight of the inguinal, axillary and mesenteric lymph nodes and of the thymus. Simpson and co-workers⁶³ found that the administration of purified adrenocorticotrophic hormone to 6 normal rats resulted in a striking reduction in weight and size of the thymus gland and the cervical lymph nodes as compared to the weight and size of these structures in six untreated controls. This was also readily apparent in 5 treated hypophysectomized animals as compared to 5 untreated hypophysectomized controls, but was not true in 10 adrenalectomized animals when these were compared with untreated adrenalectomized controls. Dougherty and White¹⁴ in an elaborate and intensive study described marked histologic changes in thymic and lymphoid structures of rabbits and mice following administration of adrenocorticotrophic hormone and a variety of adrenal cortical preparations and steroids. The changes did not occur in adrenalectomized animals treated with adrenocorticotrophic hormone nor did they occur in animals given desoxycorticosterone alone. These histologic alterations were grouped by these authors into three stages: (1) The stage of degeneration characterized by pycnosis of medium and small lymphocytes, edema of lymphatic structures, cessation of mitoses and diminished numbers of lymphocytes in nodes. This stage lasted approximately six hours, (2) the stage of repair beginning at six hours and characterized by phagocytosis of debris, and the presence of increased numbers of histiocytes and giant cells, (3) the stage of recovery beginning at about nine hours in mice and characterized by mitoses of remaining lymphocytes, maturation of reticular lymphocytes, and restoration of normal structure.

The occurrence of a similar involution of thymus and lymphoid tissue has long been recognized to follow injurious stimuli known to result in increased adrenal cortical hormone production and hypertrophy of the adrenal cortex. Bardeen,³ in 1897, observed striking alterations in lymphoid structures throughout the body in autopsy material from patients dying of extensive superficial burns. He commented on the striking similarity of these changes to those produced experimentally in animals by injection of diphtheria toxin, ricin, and other so-called toxalbumins. He also noted similar changes in the lymphatic organs of children dying of diphtheria and other febrile illnesses in which toxemia is thought to be prominent. These findings in burned subjects were confirmed by Pack.⁶⁴ Akaiwa and Take-shima² observed degenerative changes in shielded lymphoid tissue following radiation to other areas. Barnes and Furth⁴ made similar observations which they assumed to be due to nonspecific factors carried from damaged tissue by way of the circulatory system. Le Blond and Segal¹³ felt that these changes in unexposed lymphatic tissue after radiation were similar to those described by Selve⁶⁹ in the alarm reaction after a wide variety of injurious stimuli. They found that this thymic and lymphatic atrophy in unexposed areas was suppressed by adrenalectomy though the general lethal effects of the rays were increased. The observations of Selve⁶¹ and of Foglia and Selve²⁷ called attention to the fact that injurious

stimuli of many types resulted in thymic involution and hypertrophy of the adrenals, and that none of these stimuli were effective in producing similar changes in the thymus of adrenalectomized animals. Invariable histologic changes were found present in the thymus, spleen and lymph nodes of normal animals after the administration of adrenalin, formaldehyde, morphine, and atropine, and after spinal shock, surgical shock, cold and exercise.⁶⁰ Frank²⁸ confirmed substantial atrophy of the thymus and increase in adrenal weight in rats subjected to spinal cord transection. Zeckwer⁷⁴ found that loss of weight of thymus and lymph nodes resulted in rats injected subcutaneously with formalin irrespective of previous castration, thyroidectomy or thyroid feeding. Dougherty and White^{18, 71} showed that lymphoid tissue involution produced by inanition was mediated by the adrenal cortex. The evidence that a variety of injurious stimuli cause involution of lymphoid and thymic tissue and that this is dependent upon an intact hypophyseo-adrenal system is more elaborately summarized by Selye⁵⁹ in a recent review. Suffice it to say here that the evidence is extensive, well documented and that there is little in the way of dissenting studies.

Summary and discussion

It appears reasonable therefore to regard as proved that adrenal cortical hormone is capable of producing gross and histologic changes of an involutionary nature in lymphoid and thymic structures. The weight of protocols supporting this thesis, the lack of conflicting evidence, and the almost complete unanimity of opinion in this regard leave little doubt as to its validity. It can probably be safely assumed that augmentation of adrenal cortical hormone (more particularly the sugar controlling hormone) is reflected by loss of weight of lymphatic structures and the thymus, that diminution in the amount of this hormone elaborated results in increase in weight and hyperplasia of these structures, and that involutionary alterations can be produced in the intact but not the adrenalectomized animal by appropriate injurious stimuli.

The translation of these well established observations into terms of lymphoid tissue function is more difficult. That such structural changes occur is undoubted. Why they occur and just what they mean are more abstruse questions. It has been suggested¹⁴ that these structural changes represent a mechanism for liberating the metabolically important contents of lymphocytes in increased amounts during a period of stress. Increased rate of dissolution of lymphoid tissue has been assumed to contribute to the normal defense of the stressed organism in at least three ways:¹⁴ (1) Increased release of globulin from lymphocytes—possibly providing precursors for carbohydrate synthesis, (2) release of antibody globulin in the immunized animal, (3) increased production of macrophages in lymphoid structures. However, the relationship of structural changes in lymphoid tissue to other events resulting from variations in adrenal cortical activity is of necessity one of inference, and final proof must rest on the conclusive demonstration that a cause and effect relationship exists between morphologic alterations in lymphoid structures and other changes attributable to adrenal cortical hormone.

C EVIDENCE FOR ALTERATIONS IN THE NUMBERS OF THORACIC DUCT LYMPHOCYTES IN ANIMALS AFTER ADMINISTRATION OF ADRENAL CORTICAL HORMONE OR ADRENOCORTICOTROPIC HORMONE

The evidence for hormonal effects on the numbers of thoracic duct lymphocytes is, to the authors' knowledge, confined to three investigations. One of these is the study reported in Part I of this paper. The subject has been discussed in detail in

the experimental section of this report and it would be redundant to again review it here. Suffice it to say that an effect of adrenal cortical hormone on the numbers of thoracic duct lymphocytes or flow of thoracic duct lymph cannot be regarded as proved. The studies in this laboratory failed to demonstrate any significant effect of adrenal cortical extract on the thoracic duct lymphocyte in contrast to the earlier reports suggesting such effects exist.

EVIDENCE FOR ALTERATIONS IN THE NUMBERS OF BLOOD LYMPHOCYTES ATTRIBUTABLE TO AUGMENTATION OF AND DIMINUTION IN THE AMOUNT OF AVAILABLE ADRENAL CORTICAL HORMONE

Review of Medical Literature

Evidence for adrenal cortical control of the level of circulating blood lymphocytes takes origin from many sources. Most of the experimental work reported has been in mice and rats, a little in rabbits, a very little in man.

Recently De LaBalze, Reifstein, and Albright¹⁰ analysed the blood counts of 10 patients with Cushing's Disease, 20 patients with Addison's disease, and 20 patients with panhypopituitarism. Total and differential leukocyte counts were done by the hospital staff or laboratory technicians. The average white blood cell count and average absolute neutrophil count were found to be high in Cushing's disease, while the absolute lymphocyte count was low (1500 per cu mm) but within the accepted normal range. In all other groups the average figures for these factors were within the normal range. Population studies indicated that the patients with Addison's disease tended to have lower leukocyte and absolute neutrophil counts than patients with Cushing's disease. The *relative* per cent of lymphocytes was below 20 in all cases of Cushing's disease, was 25 to 35 in 8 cases of Addison's disease and over 35 per cent in 11 cases. It is well to point out that the 20 cases of Addison's disease could most certainly not be separated from *normal* individuals on the basis of the numbers of circulating lymphocytes, that while the absolute lymphocyte counts in Cushing's disease showed a tendency to be low these patients had concomitant leukocytosis and neutrophilia, and that by far the most striking difference between the two conditions was found in the average absolute neutrophil counts (4403 per cu mm in Addison's disease, 9299 per cu mm in Cushing's disease).

In addition to these human studies relating to the blood lymphocytes in disturbances of adrenal cortical function, a number of observations have been made in experimentally adrenalectomized animals. In 1928, Zwemer and Lyons⁷⁵ observed a decrease in polymorphonuclear leukocytes and an increase in the per cent of small lymphocytes in 7 cats surviving bilateral adrenalectomy for more than four days. This relative shift in leukocyte distribution did not occur till about the fourth day, leukocytosis with neutrophilia being the rule before that time—particularly in animals surviving less than four days. In 1932, Corey and Britton⁶ suggested a *neutrophilogenic failure to account for extreme reductions in total leukocyte and neutrophil counts in the adrenalectomized cat*. In one animal the relative neutrophil count fell to 3 per cent. These alterations of course resulted in an increase in the per cent of lymphocytes, but the striking blood changes involved the neutrophil. Data from this laboratory on blood counts of cats before and after adrenalectomy are presented in Part I of this paper. They did not confirm the earlier work and failed to demonstrate significant changes in absolute lymphocytes in the cat after adrenalectomy. The discrepancy between this and the earlier work is not explained but it is suggested that possibly the occurrence in the latter of infectious feline agranulocytosis (a condition not known at the time of Corey and Britton's work) in animals during the postoperative period could result in the blood picture found. Simpson and co-workers,⁶⁴ in 1934, published a few observations on blood counts of adrenalectomized rats. They found no significant change from controls in either total leukocyte count or per cent lymphocytes in animals suffering from chronic adrenal insufficiency. However, counts were made on only a few controls and adrenalectomized rats. The following year, Shecker, Friedman and Nice⁶⁷ published a short summary of mean values for leukocytes in the blood of adrenalectomized animals. In 34 normal rats the mean leukocyte count per cu mm was 11,319, whereas it had risen to 17,576 per cu mm just before death. In 19 rats differential leukocyte counts showed 81.2 per cent lymphocytes before adrenalectomy.

and 88.4 per cent lymphocytes immediately before death from adrenal insufficiency. The figures given compare the normal with the moribund rat. In 1940, Dalton and Masson⁹ reported data on 8 rats comparing the preoperative count with counts made twenty-four hours before death from adrenal insufficiency. There was an absolute lymphocytosis, an absolute neutrophilia, and a marked erythrocytosis, suggesting a severe degree of hemoconcentration in each case. It is again unfortunate that the comparison was made for animals in the terminal stages of adrenal insufficiency. More recently, White and Dougherty⁶⁷ have reported blood findings in adrenalectomized rats and mice. In 14 adrenalectomized mice, the lymphocyte counts per cu mm were $14,549 \pm 1514$ (means and standard errors) as compared to an average of 9584 ± 371 in 99 normal controls. Since these animals were untreated, hemoconcentration undoubtedly occurred. However, in adrenalectomized mice partially controlled with desoxycorticosterone the average lymphocyte count was $11,674 \pm 684$. The data for mice were obtained in the first five days post adrenalectomy. In the figures presented for rats no change in absolute lymphocyte count was noted until six days after adrenalectomy. Crafts⁷ was unable to demonstrate any significant change in total or differential leukocyte counts in adrenalectomized rats maintained on 1 per cent sodium chloride.

Since 1943, there have been a number of studies of the effects of adrenal cortical hormone on the blood elements. Dougherty and White,¹⁷ in 1943, found leukopenia, lymphopenia, and neutrophilia in mice administered adrenocorticotrophic hormone. This was apparent in three hours and change was maximal in nine hours after hormone administration. Similar results were obtained when adrenal cortical extract was given except that these findings occurred earlier. No such alterations resulted when adrenocorticotrophic hormone was given to adrenalectomized animals. In 25 mice receiving daily adrenocorticotrophic hormone for fifteen days, there was lymphopenia, neutrophilia, and little change in total leukocyte count. The blood picture could not be similarly altered by injection of prolactin, pitressin or serum globulin.

The following year, Reinhardt and co-workers⁶⁷ reported that two injections of 1 mg of adrenocorticotrophic hormone four hours apart resulted in lymphopenia and an increase in neutrophils in 6 rats as compared with 6 controls. In 4 dogs given adrenocorticotrophic hormone intraperitoneally, the marked leukocytosis developing and the differential cell counts obtained were not significantly different from controls given other protein substances by the same route. However, 3 dogs given 10 mg of adrenocorticotrophic hormones subcutaneously showed leukocytosis and some reduction in blood lymphocytes after six hours. Two controls showed little change in absolute lymphocytes. The controls also did not develop leukocytosis, however.

The most intensive studies of the role of pituitary adrenocorticotrophic hormone in regulating the numbers of blood elements have been made by Dougherty and White.¹³ Observations were reported in mice, rats, rabbits and a few in man. In mice single injections of adrenocorticotrophic hormone were given, groups of animals bled at intervals after injection, and the average cell counts compared with controls. Results indicated a substantial lymphopenia developed within one to three hours. This attained a maximum at nine hours and returned to normal by approximately twenty-four hours. In rats similarly studied, absolute lymphopenia and leukopenia were apparent at three, six and nine hours after injection and these were still present up to twenty-four hours. In rabbits, considerable lymphopenia was found up till twenty-four hours after injection. Desoxycorticosterone did not produce similar changes. In most instances, an increase in granular leukocytes accompanied the lymphopenia. Adrenocorticotrophic hormone was reported to cause neutrophilia but not lymphopenia in adrenalectomized animals. It was also stated that other protein substances will produce leukocytosis but not lymphopenia. In the same groups of studies, lymphopenia was observed in mice, rats, and rabbits receiving a single dose of 0.5 cc, 2.0 cc, and 5 cc of adrenal cortical extract respectively. In 5 human cases not suffering from Addison's disease, 20 cc of aqueous adrenal cortical extract were administered subcutaneously and blood counts made three and six hours afterwards. The results were equivocal, showing slight reduction in absolute lymphocyte counts after injection. However, the data must be viewed with some question since erythrocyte counts in the six hour period following hormone injection showed extreme unphysiologic variations in 2 of the 5 cases. Counts in both of these individuals varied from less than four to over five million per cu mm without similar changes in the hemoglobin values.

Elmadjian and Pincus²⁵ obtained blood lymphocyte values at intervals throughout the day on a small group of normal and psychotic patients. A regular diurnal rhythm was reported in normal but not in psychotic subjects. This was said to correlate with 17 ketosteroid output in urine, the latter being greatest when the lymphocyte counts were lowest. An irregular ketosteroid pattern was observed in psychotics.

Yoffey and Baxter²² in 1946 found a reduction in absolute lymphocyte counts in rats after injection of adrenocorticotrophic hormone or adrenal cortical extract. No mention was made of the total leukocyte values in this group. In 8 rats receiving daily injections of adrenocorticotrophic hormone, adrenal cortical hormone, or both for twenty-eight days, the lymphocyte count twenty-four hours after the last dose was elevated in 3 animals and depressed in 5. The significance of counts made as long as twenty-four hours after the last injection is, of course, open to question. In 2 rabbits subjected to a twenty-two day control period followed by daily subcutaneous injection of adrenal cortical extract, no appreciable change in absolute lymphocyte count was obtained.

Very recently, a detailed study at the Mayo Clinic⁴⁶ has been reported on the results of the administration of anterior pituitary adrenocorticotrophic hormone to a young woman maintained on a constant diet. The total daily dose was 25 mg for six days, 50 mg for six days, and 100 mg for eleven and one-half days. Changes in lymphocyte count were regarded as of questionable significance and the plasma electrophoretic pattern remained unchanged during the entire period of study.

Harlow and Selye,³¹ in 1937, reported leukocytosis with relative and often absolute lymphopenia in rats and mice given adrenalin or formaldehyde or exposed to cold or surgical shock. The changes in the blood picture during the alarm reaction which has been demonstrated to elicit increased adrenal cortical activity have been recently summarized by Selye.⁵⁹ The occurrence of neutrophilic leukocytosis with accompanying lymphopenia was emphasized.

A few studies are available on the effects of adrenal cortical activity on leukemia in animals. Murphy and Sturm,⁴⁹ in 1943, observed that adrenalectomy substantially increased the percentage of takes of a transmissible leukemia in rats. The same authors⁵⁰ found increased survival when rats of highly susceptible strain were treated with adrenal cortical preparations following intraperitoneal inoculation of leukemic cells. Law and Speirs⁴⁰ noted a decrease in total lymphocytes and in the immature lymphocytes of mice with spontaneous lymphoid leukemias after intraperitoneal or subcutaneous injection of adrenal cortical extract (aqueous) or lypoadrenal extract. Regression of infiltrated thymuses and lymph nodes and to a lesser extent of the spleen was observed. In the small series of animals studied, the effect on life expectancy could not be stated.

Summary and Discussion

There is considerable evidence to suggest that in mice and rats the administration of appropriate amounts of adrenocorticotrophic hormone, adrenal cortical hormone, or the stimulation of the adrenal gland by "alarming" the animal results in the production of some degree of absolute lymphopenia. There is somewhat less evidence that this applies to the rabbit, only equivocal evidence that it applies in the dog, and scant evidence thus far for its application to man. Recently, Dougherty and White²¹ have reported receiving personal communications to the effect that changes of this nature have been observed in man. In most instances, the lymphopenia has been accompanied by neutrophilia. More work is needed on the nature of the frequently reciprocal behaviour of the granular leukocyte and the lymphocyte. It is perhaps unfortunate from the standpoint of critical review that so many of these studies have been conducted on the mouse and rat, animals in which the lymphocytes constituted 60 to 90 per cent of the blood leukocytes in contrast to certain other mammals, including man, in which the neutrophil/lymphocyte ratios is the reverse of this. These experimental animals, because of their size and ready availability, are admirably suited for group hematologic studies. However, the differences in blood picture from that seen in man raise the question as to how literally observations in these animals can be applied to man. Be that as it may, in summarization it is fair to state that there is some evidence that absolute lymphopenia does result after augmentation of adrenal cortical hormone.

Conversely, the evidence for lymphocytosis resulting from diminution in the amount of available adrenal cortical hormone is at present none too satisfactory. Observations in adrenalectomized animals have been scanty and frequently open to the criticism that comparisons were made between normal animals and animals in which severe derangement of many types had occurred with extreme symptoms of adrenal insufficiency. Further, not all observers have reported absolute lymphocytosis and lymphocytosis, when observed, has not always been of striking nature. It is not clear that the absolute lymphocyte counts of patients with Addison's disease differ from those of normal individuals. It is the opinion of the authors that the present available evidence admits some reservation that the regulation of the numbers of blood lymphocytes is under pituitary control and mediated by way of the adrenal cortex.

EVIDENCE OF ALTERATIONS IN FACTORS ASSOCIATED OR PRESUMED ASSOCIATED WITH LYMPHOCYTE AND LYMPHOID TISSUE FUNCTION ATTRIBUTABLE TO AUGMENTATION OF OR DIMINUTION IN THE AMOUNT OF AVAILABLE ADRENAL CORTICAL HORMONE

Review of Medical Literature

The functions of the lymphocyte have been the subject of much speculation and discussion. Drinker and Yoffey²² summarized the available information up to the time of the publication of their monograph (1941) and were inclined to agree with Lewis that while the functions of lymphocytes were the subject of religious beliefs, reliable factual information as to their specific functions was sparse. However, lymphoid tissue has long been suspected of playing a role in serologic immunity. McMaster and Hudack⁴⁷ summarized the literature in this regard in 1935, presenting also evidence of their own that agglutinins were formed within the draining lymph nodes of mice following intradermal injection of killed cultures of micro-organisms. These authors were careful to point out that their experiments threw no light upon the subject of antibody formation elsewhere in the body. They felt that there is no good reason to consider the lymph nodes as the sole site of antibody formation. The subject was again reviewed by Drinker and Yoffey in their monograph.²²

Since 1940, further evidence has accumulated to support the suspicion that lymphoid tissue and lymphocytes may be one of the factors concerned with the production of serum globulin and antibodies. In the study of Ehrlich and Harris,²³ antigens were injected into the footpad of rabbits and the subsequent formation of antibodies in the single popliteal node draining the area was compared with the output of lymphocytes in the efferent lymph from this node and with morphologic changes in the node. Antibodies were found to appear in the efferent lymph two to four days after injecting antigen and reached their height after six days. The rise in serum titer was preceded by a sharp rise in the output of lymphocytes in the efferent lymph and by hyperplasia of the node. The authors felt the evidence pointed to the lymphocyte as a factor in the formation of antibodies.

Dougherty, Chase and White,¹⁶ two years later, extracted the washed cells from minced pooled lymphoid tissues of immunized and nonimmunized mice and also made extracts of nonlymphoid tissues. Extracts of lymphoid tissue from immunized mice showed high titers of antibodies. No titer was found in extracts from salivary glands or muscles of immunized animals nor from lymphoid tissues of nonimmunized animals. The authors concluded that antibodies are concentrated in lymphocytes. The actual production of antibodies by lymphocytes has not been established.

Kass,³⁹ in 1945 studied the thoroughly washed lymphocytes from lymph nodes removed from a patient one hour after death. Although the cell suspension of lymphocytes was washed until the supernatant would not react with rabbit antisera prepared using highly purified human gamma globulin as antigen, the extract of the lysed cells themselves reacted to anti-human globulin rabbit sera. When mixed with antisera, this extract inhibited the ability of the antisera to precipitate human gamma globulin or serum.

In the same year, Harris and co workers⁵⁷ observed that cell extracts from the popliteal node draining a site of antibody formation in the rabbit contained significantly higher titers than efferent lymph plasma. The greatest difference between cells and lymph plasma was found five days after the injection of antigen. These results were interpreted to indicate either (1) lymphocytes are a source of antibody formation or (2) lymphocytes absorb or adsorb antibody. Evidence was presented favoring the first view since lymphocytes both *in vivo* and *in vitro* were demonstrated not to pick up antibodies with which they were placed in contact.

With this as background, efforts have been made to correlate serum globulin and antibody titer changes with the postulate of the adrenal cortical control of lymphoid tissue and the blood lymphocyte level. White and Dougherty⁶⁹ found a slight but statistically significant rise in serum proteins in rats three and six hours after administration of adrenocorticotrophic hormone. This was back to normal within twenty-four hours. Daily administration of adrenocorticotrophic hormone for fifteen days produced serum protein levels somewhat above that of controls. It was thought that lymphocytes were the source of the serum protein rise. The same authors⁶⁸ in a more extensive report obtained a statistically significant increase in total serum protein of rabbits in the twenty-four hour period following administration of 10 mg of adrenocorticotrophic hormone or 5 mg of adrenal cortical steroids in oil. This was found due to an increase in the beta and gamma globulins. Cell extracts of lymphoid tissue were also found to have protein components identical with gamma globulin of serum. The authors concluded that this evidence in conjunction with observation on the lymphoid tissues and blood lymphocytes justifies the assumption that the rate of release of protein from lymphocytes is under the normal physiologic control of the pituitary adrenocorticotrophic hormone which exerts its influence by way of the adrenal cortex.

Dougherty, White and Chase,¹² in 1944, reported an increase in antibody titer after a single injection of adrenal cortical extract in 8 rabbits whose titer could not be further elevated, by injections of antigen alone. *In rabbits immunized with sheep erythrocytes final agglutinin titers were higher if adrenal cortical extract was administered together with the antigen.*

The same workers¹⁶ produced an anamnestic reaction in rabbits and mice following a single injection of adrenal cortical extract or adrenocorticotrophic hormone. Toxic stimuli such as benzene and potassium arsenite, produced an anamnestic response in normal but not in adrenalectomized mice. It was concluded that the data established the role of pituitary-adrenal secretion as the controlling mechanism for the release of antibody from lymphocytes. The anamnestic reaction is a manifestation of this control. The following year, Dougherty, White and Chase¹⁹ found that lymphocytes obtained by extraction of cells from rapidly growing mouse lymphosarcoma in immunized animals contained antibody. The antibody-containing tumor could be transplanted into a second generation of mice and antibody was subsequently found in the normal lymphocytes of the animal in which the transplant was made. It is interesting that antibody was found in the presumably normal lymphocytes of the animals who had never been exposed themselves to antigen.

Chase, White and Dougherty,⁶ in 1946, presented evidence that in mice, rats and rabbits antibody production reached a higher maximal level when adrenal cortical extract was injected with antigen. In rabbits hyperimmunized to sheep erythrocytes, a single subcutaneous injection of adrenal cortical extract produced an increase in antibody titer. The elevation in titer in most experiments was of the order of one tube when converted to terms of the usual double dilution technic. However, the trend in all experiments appeared to be uniformly upward. Continued daily injection of adrenal cortical steroids in oil were reported to maintain higher titers than those seen before hormone administration. Eisen and co workers,⁷¹ on the other hand, found no difference in either antibody titers (sheep cell agglutinins and hemolysins and precipitins against pneumococcus capsular polysaccharide or serum gamma globulin) in adrenal ectomized rats receiving adrenal cortical lipoeextract from similar animals receiving only desoxycorticosterone. Studies with glycine tagged with heavy nitrogen showed no differences in the rate of nitrogen metabolism in serum proteins in the two groups.

The effect of roentgen radiation, known to be highly destructive to lymphoid tissue has also been investigated in connection with hormonal control of release of protein and antibody from lymphoid tissue.^{71, 72} Whole body radiation in the amount of 200 r was found to elevate total serum proteins and gamma globulin and to produce an anamnestic response in previously immunized adrenalectomized mice.

The much smaller dose of 10r produced the same physiologic alterations including the anamnestic response in normal but not in adrenalectomized mice. It was felt by the authors that small doses of radiation exert their action on lymphoid tissue by augmenting pituitary-adrenal cortical secretion while large doses produce their effect without endocrine mediation.

Recently, Gjessing and Chanutin²⁹ have reported the results of electrophoretic analysis of plasma and plasma fractions of normal rats and rats subjected to thermal injury. The injured rats exhibited a decrease in the per cent of gamma globulin and albumen fractions. Alpha and beta globulins were increased. These authors report that their unpublished observations indicate that similar changes occur in the dog and that these injury patterns of Fraction II and III were also observed after administration of terpineol or of adrenal cortical hormone. In other studies involving the Tiselius apparatus, Lewis and McCulloch⁴⁴ found a decrease in gamma globulin and albumen in 8 cases of Cushing's syndrome. Li and Reinhardt⁴⁵ could detect no increase in the gamma globulin fraction of plasma of either hypophysectomized or normal rats administered adrenocorticotrophic hormone. The albumen fraction was increased. The protein components of cervical duct lymph in these animals was not altered by adrenocorticotrophic hormone. Nitske and Cohen,⁵¹ employing methanol fractionation, were unable to demonstrate statistically significant alterations in the serum proteins of a group of 12 patients with lymphocytic leukemia.

Summary and Discussion

There is rather strongly suggestive evidence that lymphocytes or lymphoid tissue may be a source of gamma globulin and play a role in antibody formation. There is some evidence that in certain species antibody titers may be enhanced and that anamnestic responses of considerable magnitude may be elicited by the administration of adrenal cortical hormone. The demonstration of significant changes in plasma gamma globulins after hormone administration requires further confirmation. Increases in gamma globulin reported have been relatively small and other observers have found decrease in gamma globulins after stress²⁹ or no changes after administration of adrenocorticotrophic hormone.⁴⁶ Further, some investigators^{23,47} have found that antibody production is accompanied by histologic hyperplasia of lymphoid tissue rather than by involutionary changes, and impairment of antibody production in the adrenalectomized animal has not been consistently demonstrated. Joffe³⁸ and Grollman³⁰ review evidence that, if anything, antibody production in adrenalectomized animals is increased. Chase, Dougherty, and White⁵ point out that the matter is controversial.

The hormones of the adrenal cortex have manifold metabolic activities. It is difficult at the present time to regard as proved that the reported changes in plasma globulins and antibody titers necessarily have resulted from lymphocyte dissolution or that the release of antibody is normally under adrenal cortical control. Further work will have to be done before this important point can be settled.

GENERAL SUMMARY AND DISCUSSION

The hormonal control through the hypophyseo-adrenal cortical system of lymphoid tissue structure and function is an important concept. We cannot at the present time regard that the concept is established fact. Final judgment must await additional work and the clarification of some of the inconsistencies which appear to exist. It seems reasonable that lymphoid tissue is one of the end organs of adrenal cortical hormone and that it may perhaps play a role in the response of the organism to stress. It seems quite clear that the sugar hormone of the adrenal cortex is capable of producing structural alterations in lymphoid tissue. Change

in thoracic duct lymphocyte numbers as a result of augmentation in the amount of available adrenal cortical hormone is at present controversial. Experiments in this laboratory have failed to demonstrate it. The production of lymphopenia, at least in some species and possibly in man, by increasing available sugar hormone is supported by some evidence. The exact mechanism of production of lymphopenia is open to question, its relationship to changes in lymphoid tissue structure being one of inference. The converse situation—absolute lymphocytosis resulting from deprivation of adrenal cortical hormone—is the subject of controversial reports. At best, it must be admitted that relatively slight alterations from the accepted normal range of lymphocyte values occur in the adrenal insufficient organism. Changes in plasma gamma globulins and antibody titers associated with changes in the amount of available cortical hormone are reported. It should be clarified whether such changes have necessarily resulted from lymphocyte dissolution or are related to other of the variegated actions of adrenal cortical hormone.

The relationship of adrenal cortical hormone to lymphoid tissue and lymphocytes and the relationship of the latter to the response of the organism to stress must indeed be complex. It is reasonably well established that the life span of the lymphocyte is very short indeed^{1 58 22} and each lymphocyte presumably liberates its metabolically important contents within a few hours at the most. If stress continues for any period of time, as often it does, it is difficult to visualize the wisdom of interfering with the production of metabolically vital substances in order to secure the transient benefits of lymphoid tissue dissolution. It is also somewhat difficult to regard as proved that the various changes reported after hormone augmentation or deprivation necessarily represent the *normal* mechanism by which these factors are regulated and kept within physiologic limits. More investigations are required to answer such questions and to further elucidate the interrelationship of the adrenal cortex and lymphoid tissues.

CHANGES IN CIRCULATING LEUKOCYTES INDUCED BY THE ADMINISTRATION OF PITUITARY ADRENOCORTICOTROPHIC HORMONE (ACTH) IN MAN

By A GORMAN HILLS, M D , PETER H FORSHAM, M D , AND
CLEMENT A FINCH, M D

INTRODUCTION

IN THIS communication we report observations on the hematologic effects of adrenal stimulation by pituitary adrenocorticotrophic hormone (ACTH). Experiments by other investigators^{1 2 3} have demonstrated that circulating leukocytes in animals are subject to the influence of the adrenal cortex. The aim of this study has been to clarify, by direct stimulation of the adrenal cortex, the nature of the control exerted upon the leukocytic pattern by adrenal cortical secretion in man, and in this way to throw some light upon the mechanism of leukocyte alterations in Addison's disease, as well as in conditions characterized by adrenal overactivity.

METHODS

The preparation* employed in this study was a purified adrenocorticotrophic hormone derived from hog pituitary by isoelectric precipitation in the cold. Its potency is attested by the fact that intravenous administration of 2 to 4 micrograms into a hypophysectomized rat provoked a marked decrease in the ascorbic acid content of the adrenals. Electrophoretic analysis revealed the presence of more than one component. The material had 0.12 units of oxytocic activity and 0.1-0.2 pressure unit per milligram, growth promoting, gonadotropic and thyrotropic factors were not present in significant amounts. It is a white amorphous powder which is soluble to at least 5 mg per milliliter of saline, although some lots require either slight alkalization or acidification for complete solution. It was handled with sterile precautions and dissolved in sterile media. No attempt was made to sterilize the material itself, as ultrafiltration results in considerable loss of biologic activity.

Smears were made directly from the needle of the syringe and prepared with Wright's stain. All other hematologic studies were carried out on oxalated venous blood. Absolute neutrophil and lymphocyte counts were calculated from the total leukocyte count and the smear differential.

Eosinophils were enumerated directly according to the method of Dunger,⁴ slightly modified. By this technic, oxalated blood is drawn into an ordinary white cell pipet to the 0.5 mark. A special diluting fluid is used, consisting of 5 cc of 2 per cent aqueous eosin, 5 cc acetone and 90 cc distilled water. The hypotonicity of the solution causes the red cells to rupture, the granules of the eosinophils take up the red dye while other leukocytes remain colorless. A Levey hemocytometer

From the Department of Medicine, Harvard Medical School, and the Medical Clinic, Peter Bent Brigham Hospital, Boston, Massachusetts.

This study was aided in part by grants to Dr. George W. Thorn from the Committee on Research in Endocrinology, National Research Council, and from the Armour Laboratories.

* This material was kindly supplied through Dr. John R. Mote of the Armour Laboratories, Chicago, Illinois.

(depth $\frac{2}{10}$ mm) is used and 4 chambers of 16 sq mm each are counted. Under these conditions, one counts, with normal human blood, about 10 to 35 cells in each chamber. The eosinophil count per sq mm (normal range—60 to 200) is obtained by multiplication of the average of 4 chamber counts by a factor of 6.25. The method permits a high degree of accuracy.⁵ Should it be desirable, the counting sensitivity can be doubled by merely drawing blood to the 10 mark in the leukocyte pipet.

Two technical points may be stressed. First, the pipet should be shaken only 50 to 150 times and the chamber loaded promptly, since Dungen's solution tends to rupture leukocyte membranes. Second, after the fluid has been introduced into the chamber, two to three minutes should be allowed to elapse while the granules

take up the dye. When this is done, no difficulty will be encountered in identifying the darkly stained eosinophils at a glance.

RESULTS

I. EFFECT OF A SINGLE INJECTION OF ACTH

A. Effect in Subjects without Adrenal Cortical Impairment

The effect of a single intramuscular injection of 25 mg of ACTH, given at 8 A.M., was studied in fasting human subjects. After an initial short latent period, there ensues a fall in lymphocytes and eosinophils and a rise of neutrophils, commonly resulting in an increase of the total leukocyte count. These changes are always apparent by two hours after injection, and become maximal at about four hours. There then ensues a return of the leukocytes over the next four to six hours to levels approaching the pre-injection ones. Determinations of the effect of a given dose of hormone after four hours thus represents the maximum measurable change. Significant changes are not observed under identical control conditions without hormone administration.

Determinations of the changes in circulating leukocytes found four hours after injection of 25 mg of ACTH intramuscularly in 8 normal human volunteers and in 38 patients with miscellaneous conditions are recorded in tables 1-a and 1-b. The

range of disorders represented in table 1-b is extensive, but in no patient was there any reason to suppose that adrenal function was impaired. It may be noted that the response to ACTH does not appear to depend upon the presence of the thymus or the spleen (Patient No 7 and No 14, table 1-b)

The results are displayed graphically in figure 1. There was a mean neutrophil

increase of 104 per cent (range -2 to $+248$ per cent), a mean lymphocyte decrease of 39 per cent (range -4 to -62 per cent) and a mean eosinophil decrease of 73 per cent (range -49 to -99 per cent). The maximum change in the hematocrit readings (10 patients) was a 2 per cent fall. These findings leave no doubt that ACTH exerts a significant effect upon the quantity of each of these three types of circulating leukocytes. The greater consistency of the eosinophil response is evident in figure 1.

FIG. 1

FIGS. 1, 2 and 3 Each circle represents the change, four hours after injection, in a single subject in the count of each cell type shown, expressed as per cent of the initial count. Heavy broken horizontal bars indicate the average of each group of determinations.

The changes in the leukocyte counts following hormone administration have been uniformly expressed as a percentage of the initial count. This method of expression is particularly desirable in the case of the eosinophils, where the initial counts in otherwise essentially normal individuals may vary widely, and since it can be shown that the cell decrease induced in different individuals by the same dose of ACTH is, in general, proportional to the magnitude of the initial count. This generalization is borne out by table 1 and figure 1, in which it may be seen that all essentially normal subjects exhibit a remarkably consistent eosinophil response to the administration of 25 mg. of ACTH, provided the fall is expressed as a percentage of the initial count. It seems likely that the same generalization applies to alterations in the neutrophil and lymphocyte responses, although here there is much more individual variation, and in any case the greater uniformity of the initial counts make the matter of small importance.

From animal experiments it is established that the ACTH employed has a di-

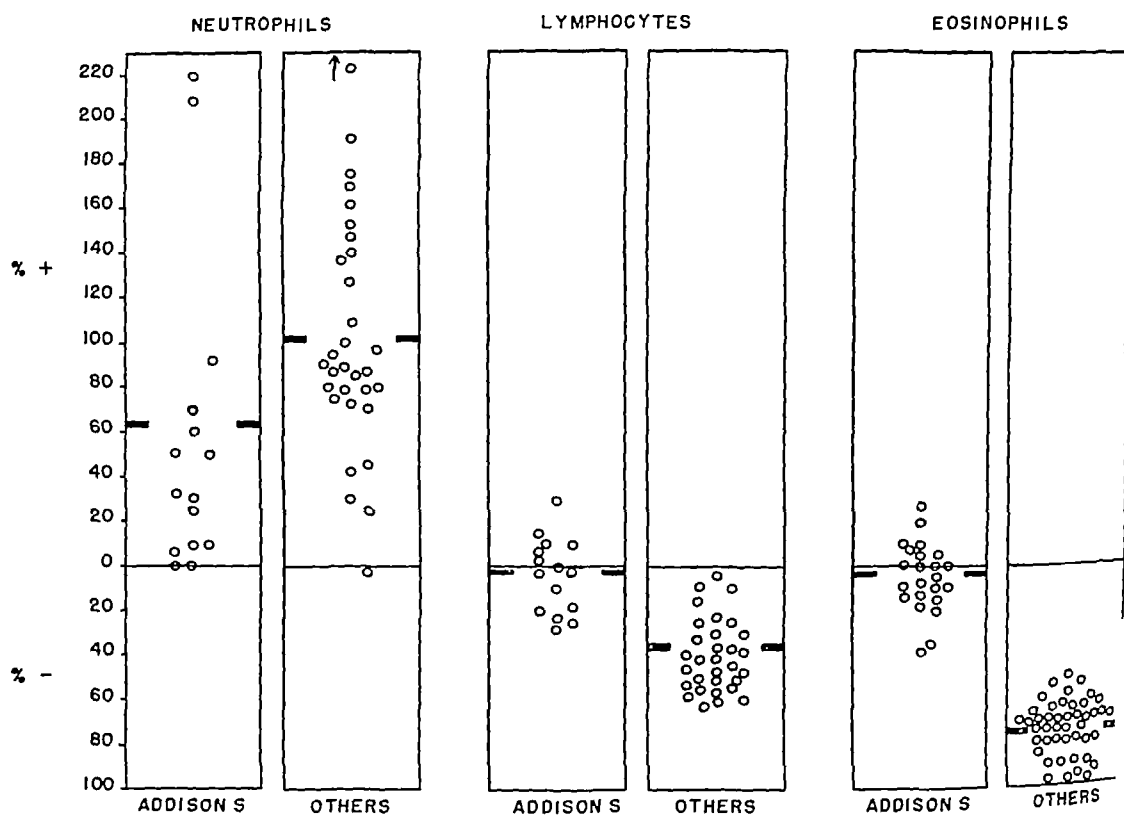

FIG 2 (see legend, fig 1)

FIG 3 (see legend, fig 1)

rect action in the absence of the pituitary. It is, however, conceivable that some of the results obtained in the study might in part at least be due to pituitary stimula-

tion by some component of the injected preparation. Since the chief contaminant of the material was posterior pituitary extract, pituitrin in amounts ten times that

present in the usual dose of ACTH was given. This produced symptoms of greater severity than observed with the ACTH preparation, but failed to depress the eosinophil to 50 per cent in three patients who had shown a normal response to ACTH.

B Effect in Addison's Disease

The leukocyte response four hours after injection of 25 mg of ACTH was also studied in 26 patients with Addison's disease, and the findings are summarized in figure 2 and table 2. There was a mean neutrophil increase of 64 per cent (range

to +220 per cent), a mean lymphocyte decrease of 2 per cent (range +31 to -28 per cent) and a mean eosinophil decrease of 4 per cent (range +20 to -38 per cent). The failure of the blood elements to respond in the usual fashion in this condition is thus very conspicuous, and the conclusion is inescapable that ACTH exerts its action on the leukocytes largely by virtue of its power to stimulate the secretion of the adrenal cortex. It is true that injection of ACTH in patients with Addison's disease, although without significant effect upon lymphocytes or eosinophils, does result in an elevation of the neutrophil count. It is apparent that the injection of this preparation promotes leukocytosis through some action other than

FIG. 4 Effect upon the leukocytes of ACTH, 10 mg intramuscularly every six hours for four days, in a normal human volunteer

stimulation of the adrenal in these patients. It will also be noted, however, that in the presence of a competent adrenal the neutrophil response is of considerably greater magnitude.

It is evident that the distinction between patients with Addison's disease and other subjects is most clear-cut with respect to eosinophils, no patient with Addison's disease showing an eosinophil decrease approaching in magnitude the smallest decrease we have observed in other subjects. This difference between the eosinophil response of the normal and the hypoadrenal subject has been utilized in a diagnostic test for Addison's disease.⁶

II EFFECT OF A SINGLE INJECTION OF ADRENAL STEROID HORMONES IN ADDISON'S DISEASE

If the failure of these patients to respond to cortical stimulation is due to lack of elaboration of cortical hormones, it should be possible to produce the changes by administration of the proper steroid. Water-soluble desoxycorticosterone was found to be without effect upon the leukocytes in a dosage as high as 30 mg intramuscularly. However, Kendall's Compound F, (17-hydroxycorticosterone),

FIG. 5 Effect upon the leukocytes of ACTH, 10 mg intramuscularly every six hours for four days,¹⁰ in adolescent girl suffering with asthenia

administered to five hypoadrenal patients in a dose of 20 mg intramuscularly, produced the entire pattern of leukocyte changes seen in normal subjects after administration of ACTH (fig. 3 and table 3). This finding is in accord with the observations of others² in animals that only steroids oxygenated at C-11 appear to be effective in this respect.

III THE EFFECT OF PROLONGED ADRENAL STIMULATION BY ACTH

The effect upon the leukocytes of more prolonged adrenal stimulation by repeated injections of ACTH (10 mg at six hour intervals), over a period of several days has also been investigated in 2 subjects with normal adrenal function on a constant dietary regimen. The neutrophilia and the reduction of eosinophils are both

striking and well sustained throughout the period of hormone administration, the lymphocytes, however, are not conspicuously depressed after the first day, and in one instance returned within twenty-four hours to their initial level and then increased beyond it. After withdrawal of hormone, eosinophils increase above pre-injection levels, and lymphocytes also reach their highest levels at this time (figs 4 and 5).

In a single subject with Addison's disease, injection of ACTH, 10 mg intramuscularly at six hour intervals for four days, resulted in no significant change in hematocrit or absolute neutrophil or lymphocyte count. The eosinophils exhibited a gradual decrease, reaching a maximum of 25 per cent on the fourth day, and returning promptly to the pre-injection level. In view of the fact that the eosinophil decrease is the most sensitive hematologic index of adrenal secretion, it may be conceived that this small and gradual decrease represented a slight residual capacity of the adrenal to respond to sustained stimulation. This supposition is in accord with the observation that patients with Addison's disease in crisis¹⁶ may show an identical response.

No striking alterations in the morphology of the leukocytes were observed in the stained blood films of the treated individuals.

DISCUSSION

Direct evidence has recently been accumulated which indicates that the adrenal cortex influences circulating leukocytes, particularly the lymphocytes. Dougherty and White have reported that adrenal stimulation by adrenocorticotrophic hormone (ACTH) in mice or rats causes a decrease in circulating lymphocytes,² tissue lympholysis^{7, 8, 9} and an increase in circulating neutrophils,² and these findings have been confirmed.³ The changes in circulating leukocytes were also produced by Kendall's Compound E (17-hydroxydehydrocorticosterone).²

Recently, Nordenson¹⁰ reported that the administration of ACTH in a single dose of 150 mg to 2 normal human beings, and a single injection of 150 mg or multiple injections totalling 212.5 mg to 2 patients with lymphatic leukemia, was without significant effect upon circulating blood cells. We are not aware of the appearance of any other publication dealing with the effect of ACTH upon the human leukocyte picture, but Dougherty and White¹¹ state that the lymphopenic action in the human of ACTH and of certain adrenal cortical preparations has been demonstrated by Darrow and by Hellman.

Physiologic mechanisms brought into play by all types of stress appear to include adrenal cortical stimulation, resulting in excessive secretion of steroids as reflected in increased urinary elimination of 17-ketosteroids and 11-oxysteroids,¹² and by blood changes resembling those obtained by administration of ACTH.¹³ Selye¹⁴ has collected an impressive body of evidence pointing to the adrenal cortex as the agency through which many of the known nonspecific reactions to stress are mediated.

That leukocytosis accompanies the widest variety of insults to the organism is a clinical commonplace, it has also been long recognized that in many such conditions there is a reciprocal relationship between lymphocytes and neutrophils.¹⁵ This

nonspecific reaction pattern of the leukocytes is impaired in patients with Addison's disease¹⁶ and in adrenalectomized animals,¹⁷ but in both instances can be produced by the administration of 11-17-oxysteroids. It appears, therefore, to be mediated, to some extent at least, by the adrenal cortex.

As far as we are aware, direct evidence has not previously been put forward that the eosinophils are likewise subject to adrenal control. Nevertheless, a wealth of reports in the literature attests the great variety of clinical emergencies in which a striking diminution of the eosinophils is found. As early as 1893, Zappert¹⁸ reported decrease of these cells as a regular manifestation of a wide variety of infections, and Staubli,¹⁵ in 1910, stressed the reciprocal relation between eosinophils and neutrophils, not only in acute infections but also following injections of nuclein, turpentine, and foreign protein. Starvation,¹⁹ ²⁰, ²¹ exposure to cold,²¹ operative procedures,²² peritonitis,²³ and injections of *B. Coli*,²⁴ sodium bicarbonate,²⁵ or ammonium chloride²⁶ have all been shown to cause marked reduction of eosinophils in animals, as have such diverse clinical emergencies in man as intravascular hemolysis,²⁷ hemorrhage, hypertensive crises, acute congestive failure, ureteral colic and various poisons.²⁸ Selye¹⁴ has included changes in circulating eosinophils among the manifestations of the "general adaptation syndrome." Evidence presented in this report indicates that the adrenal cortex is important in the production of these changes in man.

The pituitary-adrenal mechanism is only one of a number of factors controlling leukocyte levels. Neutrophilias often seen in certain bacterial infections are of greater magnitude than has been produced by direct stimulation of the adrenal by ACTH and must in all probability require one or more specific neutrophil-promoting factors in addition to the adrenal response to nonspecific stress. Similarly, striking eosinophilias and lymphocytoses cannot be explained as the result of diminished adrenal secretion since the absence of adrenal function in Addison's disease is not as a rule accompanied by alteration in the blood picture of a magnitude comparable, for example, to the lymphocytosis of pertussis or the eosinophilia of certain parasite infestations.¹⁶

The observations reported in this communication concern only the pituitary-adrenal mechanism which accounts for a part of the leukocytic changes associated with nonspecific stress. Direct information regarding the effect of adrenal stimulation upon the leukocytes in man should, we believe, be of assistance in interpreting the blood changes of certain endocrine disorders²⁹ and of all clinical conditions which bring nonspecific defensive mechanisms into action.

SUMMARY AND CONCLUSIONS

1. Pituitary adrenocorticotrophic hormone (ACTH), when administered in a single intramuscular dose of 25 mg. to human subjects with unimpaired adrenal function, results in a characteristic alteration of the leukocytic pattern. This consists of an increase of circulating neutrophils and a decrease of circulating lymphocytes and eosinophils.

2. The decrease in circulating lymphocytes and eosinophils is contingent upon the stimulation of a functionally competent adrenal cortex, and does not occur in

its absence. The neutrophilic response is present but somewhat diminished in adrenal insufficiency.

3 The entire pattern of leukocytic alterations found in normal subjects after administration of ACTH can be induced in patients with Addison's disease by 17-hydroxycorticosterone (20 mg) but not with desoxycorticosterone glucoside (30 mg).

4 Prolonged adrenal stimulation by ACTH, given over a four day period in a dose of 10 mg every six hours, results in a sustained and striking elevation of neutrophils and depression of eosinophils, the lymphocytes, after an initial depression lasting not more than twenty-four hours, may increase above their initial levels in spite of the continued increased secretion of adrenal hormones.

5 The relation of the adrenal cortex to the characteristic nonspecific leukocyte pattern, observed as a response of the organism to any type of insult, is discussed.

ACKNOWLEDGEMENTS

THE BLOOD PICTURE IN ADDISON'S DISEASE

By JOSÉ BÁEZ-VILLASLÑOR, M D , CHARLES E RATH, M D , AND
CLEMENT A FINCH, M D

RECENT observations indicate that the adrenal cortex has a controlling influence on certain elements of the peripheral blood. The present study reviews the blood picture in 100 cases of Addison's disease to determine the effect of a deficiency of adrenal cortical hormone upon the blood picture.

MATERIAL

Hematologic data were obtained from the hospital records of 100 patients in whom the diagnosis of adrenal insufficiency seemed definitely established. In the 22 patients examined at autopsy there was either atrophy or tuberculous involvement of the adrenals. Among the remaining 78 there was increased pigmentation in all but 2. Estimation of the urinary ketosteroids were performed in one-half of these patients and found to be reduced in all cases. In the 63 patients to whom specific therapy was given, the response to treatment was clear cut. Arterial hypotension, heart size, and calcified adrenals by x-ray supplied confirmatory evidence.

ORGANIZATION OF DATA

Patients were divided into three groups

<i>Group I</i>	<i>Group II</i>	<i>Group III</i>
28 patients	63 patients	9 patients
Average age 43 years	41.5 years	43 years
No specific therapy	Under replacement therapy, either desoxycorticosterone or adrenal cortical extract	Studied before and immediately after treatment

Age distribution for the 100 patients showed 4 in the second decade, 16 in the third, 22 in the sixth and 9 in the seventh. Tuberculosis was considered the causative agent in 42 per cent, whereas 58 per cent were thought to be nontuberculous. In Group I (without treatment) there were 16 tuberculous versus 12 nontuberculous patients, in Group II there was a predominance of 41 nontuberculous to 22 tuberculous patients. The average duration of symptoms of patients in Group I before admission was eight months, subsequent life span was short and frequently complicated by infection. Group II consisted of patients under treatment who had had symptoms over an average of 4.9 years.

LEUKOCYTE CHANGES IN ADDISON'S DISEASE

Lymphocytosis and neutropenia as well as a general increase in lymphoid tissue have been repeatedly observed in Addison's disease.¹ The recent work of Dougherty and White² and others has demonstrated that adrenal steroids control to a considerable extent the circulating lymphocyte level and mass of lymphoid tissue. Reifenstein and Albright³ have compared the difference in basal blood picture in Addison's disease and Cushing's syndrome and attributed this to the level of adrenal function. In view of these observations and the information obtained by direct stimulation of the adrenal cortex in man, it was of interest to examine more thoroughly the blood of patients with hypoadrenalism to determine what abnormalities might be present not only under basal conditions but under stress conditions as well.

From the Medical Clinic, Peter Bent Brigham Hospital, Boston, Mass

The most marked alteration in the leucocyte picture was found in those patients under maintenance treatment (Group II), probably attributable to the longer duration of hypoadrenalism. Leukopenia (white cell count below 5,000/cu mm) was observed in 21 per cent of the patients in this group. Lymphocytosis and neutropenia was observed in about one-half of the patients (table 1).

There was no significant difference in the level of circulating eosinophiles by direct count in twenty Addisonian patients from a control group.* There was, however, an eosinophilia (eosinophiles over 5 per cent) in 14 per cent of the patients in Groups I and II by smear. Although 10 patients had allergic histories, only 2 of these had associated eosinophilia. Allergy usually antedated the Addison's disease and with the exception of one patient with urticaria, all patients showing sensitivity phenomena had adrenal insufficiency of the nontuberculous origin.

It has been shown that adrenal stimulation by pituitary adrenocorticotrophic hormone or a variety of stress conditions produces neutrophilia, lymphopenia and a decrease in eosinophiles in the patient with normal adrenal function.⁴ Adrenocorticotrophic hormone does not produce these changes in the Addisonian. The same should be true of stress reactions, either infection or crisis, assuming the hematologic change of stress to be mediated through the adrenal cortex. The blood

TABLE 1 — *Relative Lymphocytosis*

	% over 35%	% over 40% of total WBC
Group I (28 patients)	35	16
Group II (63 patients)	68	48

picture in tuberculous versus nontuberculous Addisonians was identical except for a slight neutrophilia in the former (table 2). The changes in crisis and infection are likewise insignificant except for some decrease in eosinophiles (tables 3 and 4). The absolute lymphocyte count remains remarkably constant and leukocytosis is suppressed. It is evident that the usual leucocyte response to stress is lost in hypoadrenalism.

As an explanation for the drop in eosinophiles, it would seem likely that the stress reaction produces a stronger stimulus for oxysteroid excretion by the adrenal than did the single injection of adrenocorticotrophic hormone. Repeated doses of ACTH have produced in Addison's disease a depression of eosinophiles when single doses have failed. The eosinophile is by far the most sensitive of the blood elements in its response,⁴ and since no change occurred in the other elements we might suppose that adrenal excretion was very slight. The adrenocortical extract given in treatment of the crisis, in some instances, may have contributed to the response.

There was no recognizable effect of the maintenance treatment given on the white cell picture. Patients in Group II were carried for the most part on desoxy

* These data may be found in tables 1 and 2, *Changes in Circulating Leukocytes Induced by Pituitary Adrenocorticotrophic Hormone (ACTH) in Man*, by Hills, A. G., Forsham, P. H., and Finch, C. A. See *Blood*, this issue, pp. 756, 761.

corticosterone by injection or by pellet implantation. As previously described, the changes in the blood picture in this group were actually more pronounced than in patients before the advent of specific therapy. Daily maintenance dose of adrenal extract (5 cc Eschatin) and small amounts of Lipo-Adrenal Cortex* did not change

the blood picture. It has been found⁴ that single doses up to 30 mg of desoxycorticosterone have no effect on the blood picture while 20 mg of Compound F (Kendall) results in definite eosinophile and lymphocyte alterations four hours after administration. It seems evident that only appreciable amounts of corticosteroids with the oxygen on C₁₁ and C₁₇ have the capacity to produce hematologic changes

* Whole adrenal cortical extract in oil (Upjohn Company)

ANEMIA OF ADDISON'S DISEASE

It is frequently difficult to estimate the degree of anemia in Addison's disease because of the variations in plasma volume characteristic of this disease. However, in a group of stabilized patients there was an average hemoglobin of 13.35 grams per cent. In several patients with hemoglobins of 11 to 13 grams, liver and iron therapy did not affect the degree of anemia. On the other hand, an abrupt change in blood volume, as followed treatment in Group III, results in a temporary hemoglobin depression followed by reticulocytosis and return of the hemoglobin to almost precisely the same level as was present before treatment. It would thus appear that with the general metabolic disturbance of Addison's disease, the circulating hemoglobin is set at a lower level.

TABLE 5

	Hgb gm/100 cc	Avg	Range
<i>Group I</i>			
Men	14.2	13.2	9.4 to 18
Women	12.6		
<i>Group II</i>			
Men	13.4	13.3	9.1 to 17
Women	13.3		

TABLE 6

	Hgb/gm	Hct	Rbc
<i>Group III</i>			
Before treatment	13.7	41.6	5.1
After treatment	10.7	32.5	3.8
Averages, % decrease	21.5%	22%	25%

The anemia found in Addison's disease is normocytic and normochromic. In 40 patients of Group II, the average mean corpuscular volume was 92 cubic micra, mean corpuscular hemoglobin 32 micra micrograms, and mean corpuscular hemoglobin concentration was 34.8 per cent. In a small series in which careful cell measurements were made, the same normal cell indices were found. There was no difference in the degree of anemia between tuberculous and nontuberculous patients. In Group I, there was a sex difference not seen in Group II. This might suggest that in the first group, due to the short duration of the illness, the pre-existing sex difference was maintained, and that in Group II this difference had disappeared.

The values for formed elements of the blood in untreated Addison's disease are deceptive because of the markedly contracted blood volume (table 5). Some of the patients, just as do experimental animals in crisis, showed elevated levels of hemoglobin.⁵ The actual change in blood volume following treatment may be estimated

from the hematocrit, for during this short time the red cell mass may be regarded as relatively fixed, and fall in hematocrit will be proportional to the increase in plasma volume * This change averaged over 20 per cent in the 9 patients of Group III, and, as was to be expected, was somewhat greater than that occurring in normal subjects on the same dosage ⁶

The anemia may be estimated to be about 20 per cent more severe in the untreated group than in treated patients on the basis of our findings in Group III † This is consistent with the concept that here the bone marrow responds to the relative concentration of hemoglobin in the blood rather than the total cell mass

There was no evidence of increased blood destruction Total bilirubin determinations ranged between 18 and 59 mg per 100 cc in 16 patients with an average of 33 mg per cent In 4 patients, radioactive iron was injected intravenously and the rate measured at which the tagged iron was incorporated into new red cells ⁷ The iron utilization for hemoglobin production was only slightly less than normal over a period of two to three weeks Serum iron was also within normal limits

SUMMARY

The blood picture of 100 patients with Addison's disease was analyzed Under basal conditions, there was a tendency toward lymphocytosis and neutropenia Under stress, the blood picture remained fixed The impaired ability of those patients to show leucocytosis and lymphopenia is attributable to their impaired adrenal function While large doses of desoxycorticosterone and maintenance doses of adrenal extract had no effect on the blood picture, 17-oxysteroids produce both neutrophilia and lymphopenia The anemia present in Addison's disease is normocytic and normochromic

I A PROCEDURE FOR SCREENING COMPOUNDS FOR LEUKOTOXIC ACTION

By HOWARD E SKIPPER, PH D , WILLIAM H RISER, JR , M D , ANNE
STELZENMULLER, A B , AND HELEN HOLT, A B

ALTHOUGH it is fully appreciated that agents possessing a strong leukotoxic action may not in themselves provide an answer to the treatment of leukemia, one cannot fail to be impressed by the uniformity of occurrence of this phenomenon in clinical methods of treatment which have shown some degree of usefulness against this neoplastic disease, i e , x-ray, radium, other radioactive elements, benzene, potassium arsenite, nitrogen mustards, and urethan¹⁻⁴ In view of this interesting occurrence, it appeared that information concerning molecules (particularly urethans) which possess cytotoxic specificity, especially upon the hematopoietic system, might in turn aid in the selection of compounds for further study

The present paper presents a simple and rapid technic for rough qualitative determination of the leukopenic action of a given agent, using the mouse as the experimental animal Results of hematologic studies with urethan, nitrogen mustard (HN₂)*, x-ray, potassium arsenite, and benzene are reported herein Clinical studies using urethan in the treatment of human leukemia as well as the results of leukopenic assays with some twenty-five structural variations of the urethan molecule are being reported elsewhere

The advantages accompanying the use of a small laboratory animal, such as the mouse, for screening work are obvious, however, lack of well established normals, a small blood volume, possible strain differences, and a considerable variation in the circulating leukocyte count depending on the source of blood (ventricle or peripheral), have been deterrents in the use of mice for hematologic research Attempts have been made in our studies to overcome these difficulties by standardization of the controllable variables

PROCEDURE

Carworth Farms CFW strain mice, of approximately the same age and weight with equal distribution of sexes, have been used in this study These animals were kept in an air-conditioned animal room and fed a standard diet of Purina dog chow

The first phase of the hematologic screening technic entailed determination of the acute LD₅₀ of the agent to mice by parenteral administration, using isotonic saline, 10 per cent gum acacia, propylene glycol, or peanut oil as the carrier An arbitrary ten-day observation period was selected and three points on a log-probability plot were considered sufficient for the LD₅₀ approximation

In the second phase of the study, mice of a given shipment lot were grouped and injected at the LD₅₀ level and at one-half the LD₅₀ level Five mice from each group

From the Southern Research Institute, and the Medical College of Alabama, Birmingham, Alabama

* HN₂ is a designation for the nitrogen mustard, methyl bis (2-chloroethyl) amine

were sacrificed for hematologic study at two and four or four and seven days after injection according to the following plan

Dosage	No. of Animals Injected*	Schedule for Hematologic Examination†	
		4th day	7th day
LD ₅₀	24	5	5
$\frac{\text{LD}_{50}}{2}$	12	5	5

* Numbers in excess of requirements for blood studies were injected to make allowances for deaths

† Total erythrocyte count, total leukocyte count, differential leukocyte count, and hemoglobin (Hb) determination were made in all cases. Control studies were made on each lot of mice used

Blood for all counts was obtained by anesthetizing the animal with ether and immediately drawing a fairly large sample (0.3 ml) directly from the heart in the region of the right ventricle. This operation required slightly over one minute. Early in our studies it was learned that etherizing caused a rapid and reproducible increase in the absolute circulating white count of mice.⁵ No significant shift in the differential ratio, erythrocyte count, or hemoglobin level was noted. In view of the rapidity of this increase and the lack of any observable shift in the leukocytic formula, it was assumed that the mechanism of this increase was the release of already formed elements from sites of sequestration. Statistical studies on 125 counts of etherized mice (otherwise untreated) showed a degree of consistency compatible with use of this "elevated normal" mean as a base line for leukopenic assays. All results reported herein are on etherized animals.

Blood samples were taken at approximately the same time each day. All mice were sacrificed after exsanguination. Smears and dilutions were made rapidly to prevent clotting.

Summaries of the blood studies of each group of five mice are reported as a mean. Standard deviations (σ) from the mean have been calculated and are recorded in the case of total leukocyte counts to indicate the degree of internal consistency attained in the various groups.

RESULTS

Results of blood studies on ten groups of otherwise untreated etherized CFW mice containing five animals each, which provide the base line in this report, are summarized in table 1. Included in this table is a simple statistical analysis of the data obtained.

In order to test the reliability of the screening procedure, groups of mice were given single doses at the LD₅₀ and one-half the LD₅₀ level of urethan, nitrogen mustard (HN₂), x-ray, potassium arsenite, and benzene. The leukopenic action of these compounds and of x-rays is well known, however, it was questionable as to whether single doses would produce a significant response in mice within the chosen observation periods. Toxicity data used in this experiment are listed in table 2.

* All animals were etherized before exsanguination, this produced an increase in the formed leukocytes apparently due to their release from sites of sequestration. It is assumed that this rapid release of already formed elements is operative in the treated as well as the control animals.

† In this screening procedure, lymphocytes and monocytes have been grouped under the general heading "Agranulocytes."

Results obtained using the leukopenic therapy referred to above and the four and seven day schedule for hematologic assays are summarized in table 3. Graphic presentation of the leukocyte depression obtained is presented in figures 1 and 2. In

these figures, the normal range refers to the spread observed in grouped means of normal etherized CFW mice

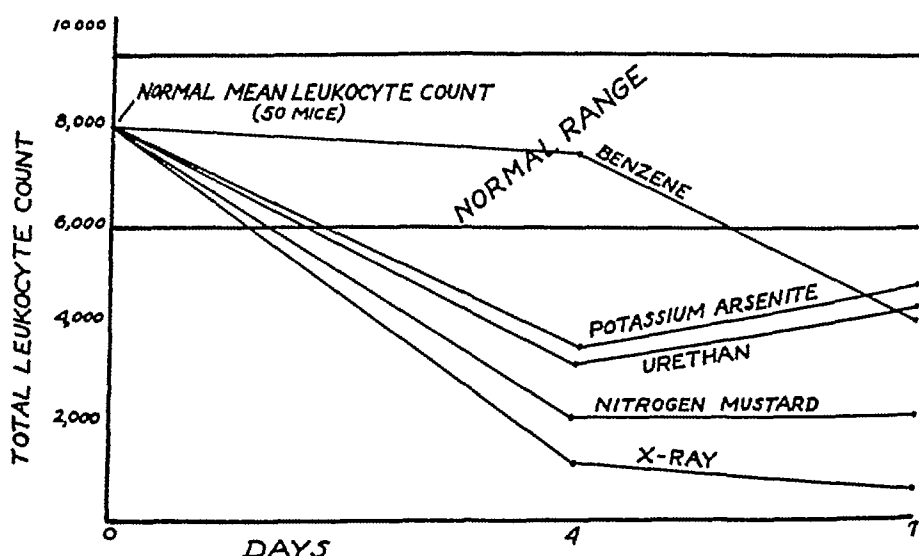

FIG 1 Leukocyte Depression Resulting from Treatment at the LD₅₀ Level (Each point represents the average of five mice)

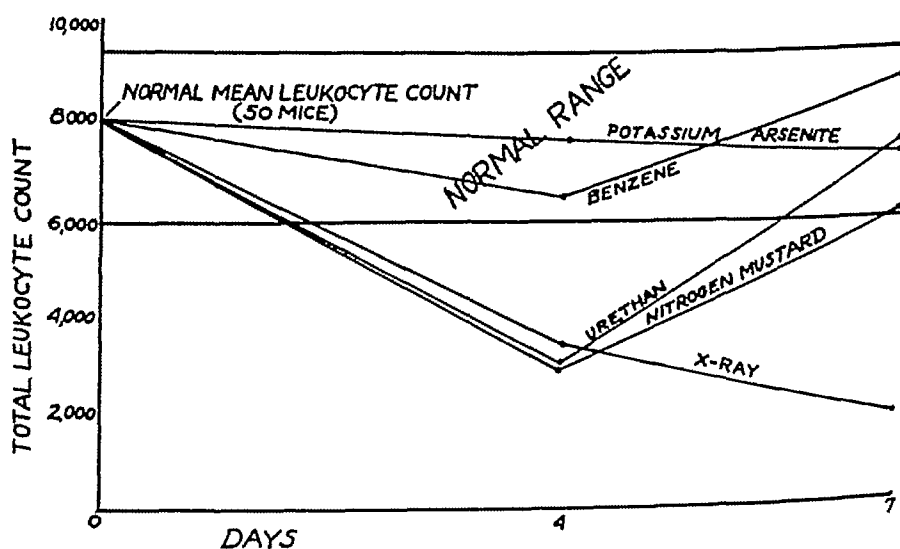

FIG 2 Leukocyte Depression Resulting from Treatment at One-Half the LD₅₀ Level (Each point represents the average of five mice)

DISCUSSION

The leukocyte counts of the 50 control etherized mice reported fit well into a normal frequency distribution curve. An additional 75 etherized controls have been studied and the results analyzed and found in good agreement with the present data. In accord with general statistical practice, it is assumed that any group of animals having a mean leukocyte count of plus or minus three standard deviations from the control mean has been significantly affected by the therapy in question. On this basis, there can be little doubt that the leukopenic action of urethan, nitrogen mustard, x-ray, potassium arsenite, and benzene has been demonstrated by the assay.

In this study, comparisons have been made at the LD₅₀ and one-half the LD₅₀

dosage levels, hence the results may be considered to indicate a leukopenic index into which acute toxicity of the agent has been taken into account

Unless a compound shows some specificity toward malignant cell repression or destruction, it may be that leukopenic action should be avoided rather than sought for in chemotherapeutic agents for leukemia. However, until considerable data is accumulated on the life span of leukemic animals treated with leukopenic and non-leukopenic compounds further belaboring this question seems futile. Our laboratory and others are carrying out such leukemic assays.

The somewhat specific mitotic depression observed in urethan leukopenia is paralleled by the cytotoxic action of this compound on epithelial cells of the crypts of Lieberkuehn. This latter action has been reported by Dustin⁷ and has been confirmed in this laboratory. It is of particular interest to determine whether the same mechanism is responsible for mitotic depression at both sites or whether certain compounds will demonstrate a specificity correlatable with chemical or physical properties of the drug. Any such specificity should provide interesting data when tested against various strains of leukemia.

The results obtained using this assay on a selected group of urethans, along with comparative results obtained with reference to the mitotic poisoning observed in the intestinal crypts, will be reported in subsequent papers. The same urethans are being assayed for anti-leukemic action against a transplantable myeloid and lymphoid mouse leukemia.

In addition, C¹⁴ tracer studies are being carried out with carbonyl- and ethoxy-tagged urethan in an effort to further elucidate the mechanism of action of this compound.

SUMMARY

A simple procedure for screening compounds for leukotoxic action is described. Results obtained on assaying known leukopenic agents such as urethan, nitrogen mustard, x-ray, potassium arsenite, and benzene indicate a reasonable measure of reliability.

ACKNOWLEDGMENT

The authors wish to express grateful appreciation to Mr. Ben May of Mobile, Alabama, for support of this project.

PARA-AMINOBENZOIC ACID IN LEUKEMIA*

By C J D ZARAFONETIS, M D, G A ANDREWS, M D, M C MEYERS,
M D, AND F H BETHELL, M D

MEASURES introduced for the treatment of leukemia have two points of interest. In the first place, any treatment which may mitigate the symptoms and prolong the useful life of persons suffering with a fatal disease of unknown etiology possesses intrinsic merit. In the second, the therapeutic trial of agents which have a demonstrable effect on the growth of leukemic cells is justifiable because of the contributions which may thereby be made to the knowledge of the pathologic physiology of the disease.

In 1944, Flory¹ reviewed the status of those forms of therapy for leukemia which up to that time had been used with varying degrees of benefit. Since then, Paterson and her associates² have presented evidence that urethane (ethyl carbamate) is capable of causing improvement, especially in patients with chronic myelogenous leukemia, and Goodman and others³ have described favorable results obtained with "nitrogen mustard" therapy in some patients with leukemia. The purpose of this communication is to present data which indicate that para-aminobenzoic acid (as sodium para-aminobenzoate) is capable of causing certain definite effects in chronic myelogenous leukemia. Since para-aminobenzoic acid (PABA) is generally considered to be a member of the B-complex group of vitamins^{4,5} and is known to be a normal constituent of many food substances,⁴ it appears to us that the following observations of its effects in leukemia are of sufficient significance to warrant publication at this time.

Para-aminobenzoic acid has been successfully employed in the treatment of the rickettsial diseases of man^{6,7}. It was apparent during the earlier studies of the clinical effects of PABA in louse-borne typhus fever that PABA inhibited the growth of rickettsiae indirectly, that is, by influencing the metabolism of the parasitized cells in some manner.⁶ During these studies, it occurred to one of us (C Z) that cells of disordered metabolic function, that is, neoplastic cells, might not be able to adapt to a substrate containing PABA in high concentration. In view of the apparent non-toxicity of large doses of PABA in typhus patients, it was judged safe to test this hypothesis in patients with leukemia.

The present report deals with the results obtained in the study of 10 patients to whom PABA was administered. Five of these subjects had chronic myelogenous leukemia, three had subacute myelogenous leukemia, of whom two were subclassified as erythroleukemia, and two had chronic lymphatic leukemia.

For administration to the patients, para-aminobenzoic acid (PABA)** was placed in solution by conversion to sodium para-amino-benzoate (NaPAB) with sodium

From the Thomas Henry Simpson Memorial Institute for Medical Research, and the Department of Internal Medicine, University of Michigan, Ann Arbor, Michigan.

** The para-aminobenzoic acid used in this study was kindly supplied by Merck and Company, Rahway, New Jersey.

bicarbonate. The final volume was adjusted to make a 10 per cent solution of NaPAB which was administered orally to the patients in 20 cc to 40 cc doses (20 Gm to 40 Gm) every two hours, day and night. The solution was taken most readily in a small amount of fruit juice or ginger-ale. The schedule of therapy employed here is similar to that used in the treatment of certain of the rickettsial diseases^{6,7}. The two-hourly schedule is required to maintain a desired blood level since this compound is rapidly excreted in the urine. Purely on an empiric basis, an attempt was made to keep the blood level of NaPAB between 10 and 30 milligrams per cent, although this level was frequently exceeded without any apparent ill effect. In some instances the dosage schedule was modified for patients who continued to take NaPAB at home. They were allowed to double the doses and the intervals between them during the night in order to obtain more rest.

CASE REPORTS (Table I)

Case 1 F G, a 45 year old white salesman, was admitted to the Simpson Memorial Institute on October 31, 1946. He had been well until May, 1946, when he noted loss of weight and progressive ease of fatigue. Symptoms of hypermetabolism were also present.

Physical examination revealed obesity and slight pallor. Several ecchymoses were present over the abdomen and lower extremities. There were no palpable lymph nodes. The liver descended 5 cm. below the right costal margin, and the spleen was greatly enlarged, extending 4 cm. to the right of the umbilicus and down two-thirds of the distance between the umbilicus and symphysis pubis.

On admission the hemoglobin was 11.0 grams per 100 cc., red blood cells 3,600,000 per cubic millimeter, and white blood cells 471,500 per cubic millimeter. The red cell packed volume was 33 per cent and the white cell packed volume was 20.5 per cent. The differential count revealed myeloblasts 0.5 per cent, promyelocytes 1 per cent, myelocytes 21.5 per cent, metamyelocytes 22.5 per cent, band neutrophils 13.5 per cent, segmented neutrophils 35.5 per cent, eosinophils 3 per cent, basophils 1.5 per cent, lymphocytes 0.5 per cent, and hemohistiocytes 0.5 per cent. Bone marrow findings were compatible with the diagnosis of chronic myelogenous leukemia. Urine analysis was negative. Fasting blood sugar was 50 milligrams per 100 cc., the blood cholesterol was 132 milligrams per 100 cc., and the basal metabolic rate was plus 28 per cent.

On November 4, NaPAB was started 2 Gm. every two hours, and increased to 4 Gm. every two hours four days later. The patient continued to receive NaPAB for twenty-seven days, taking a total of 125 Gm. During this time his leukocyte count fell from 427,250 to 25,250 per cu. mm. The red cell packed volume rose from 31.0 per cent to 35.5 per cent while that of the white cells decreased from 17.0 per cent

to 15 per cent. The hemoglobin level increased from 10.8 Gm to 11.1 Gm per 100 cc. Throughout the period of medication, there was constant glycosuria of 2 to 3 plus. The blood levels of NaPAB reached 37.2 mg per cent. The patient's spleen decreased in size during the period of therapy, and for some time after its discontinuance. On December 9, when the patient had received no NaPAB for the preceding nine days, his hemoglobin was 12.8 Gm, red cell packed volume 41.0 per cent, white cell layer 2 per cent, leukocyte count 33,050 per cu mm, with differential values essentially as before.

The patient was seen again on December 18, 1946. The spleen had enlarged considerably from the previous examination, and the leukocytes numbered 167,250 per cu mm with 9 per cent myeloblasts.

Three weeks later the leukocytes had increased to 335,000 per cu mm and there was further enlargement of the spleen. Differential count showed 11 per cent blast cells. Platelets were decreased. The hemoglobin was 9.6 Gm. The basal metabolic rate was plus 67 per cent. The patient was admitted for further treatment and was given 4 Gm NaPAB every two hours, day and night. After eighteen days, the leukocytes numbered 141,000, and the hemoglobin was 8.0 Gm. The basal metabolic rate at this time was plus

CHART 1. PATIENT F.G. 513293. AGE 45. WHITE MALE. CHRONIC MYELOGENOUS LEUKEMIA

50 per cent, and the patient had gained a few pounds in weight. He was discharged to continue taking NaPAB, 2.6 Gm daily at home. At the end of two weeks, the leukocyte count fell to 58,500 per cu mm, and the red cell values remained stationary. At this time he had 54.5 per cent blast cells. Thereafter, his leukocytes began to increase despite the continued administration of NaPAB. On February 25, after forty-two days of continuous medication, the white count was 104,750 per cu mm with 59 per cent blast forms. NaPAB was discontinued and the patient felt fairly well for two or three days, but then began to lose ground rapidly. He was readmitted on March 1, 1947. He appeared extremely ill, and was dyspneic, weak, and very apprehensive. The spleen was greatly enlarged, and the leukocytes numbered 344,000 per cu mm with 83 per cent blast forms. The patient became increasingly dyspneic and developed signs of circulatory collapse. Blood transfusion and oxygen were administered, but he died on the following day. Permission for autopsy was not obtained.

This patient received two courses of NaPAB over twenty-seven and forty-two days, respectively. He was given a total of 2,538 Gm of the drug. Glycosuria was noted during both courses of NaPAB administration. Chart 1 illustrates the changes in leukocyte counts and hematocrit values during the period of observation.

Case 2 K P (Chart 2) This 69 year old white man first experienced symptoms of exertional dyspnea, weakness, and ease of fatigue in October, 1945. In November, 1945, he was admitted to the University Hospital and the diagnosis of chronic myelogenous leukemia was made. He received a course of total body x-ray irradiation with excellent symptomatic improvement. However, weakness and fatigue reappeared in April, 1946, and he was given more irradiation therapy and several transfusions during May, 1946. He returned on October 1, 1946, and was admitted to the Simpson Memorial Institute. The patient was pale and appeared to have lost much weight. The liver was palpable 3 cm below the right costal margin, and the spleen was greatly enlarged, descending 3 cm below the umbilicus.

On admission the hemoglobin was 7.9 Gm per 100 cc, erythrocytes 2,600,000, and leukocytes 230,500 per cu mm. The red blood cell packed volume was 23 per cent, and the white cell packed volume was 10 per cent. The differential count was as follows: myeloblasts 6 per cent, promyelocytes 3 per cent, myelocytes 16 per cent, metamyelocytes 7 per cent, band neutrophils 26 per cent, segmented forms 22 per cent,

CHART 2. PATIENT K P 580337 AGE 69 WHITE MALE CHRONIC MYELOGENOUS LEUKEMIA

basophils 12 per cent, and eosinophils 8 per cent. The platelets were slightly increased. The fasting blood sugar level was 75 mg per 100 cc. The patient was given 24 Gm of NaPAB daily from October 2 to October 29 when his leukocytes numbered 38,000 per cu mm. He was discharged on October 31 and was not seen again until January 7, 1947.

The spleen now reached a point 6 cm below the umbilicus, and the liver extended 4 cm below the right costal margin. The hemoglobin was 7.5 Gm, the red cells 2,400,000, and the leukocytes 154,950 per cu mm. The red cell packed volume was 23 per cent, and the white cell packed volume was 9 per cent. The differential count revealed myeloblasts 8 per cent, promyelocytes 5.5 per cent, myelocytes 17.5 per cent, metamyelocytes 21.0 per cent, band neutrophils 17.5 per cent, segmented neutrophils 13 per cent, basophils 11 per cent, eosinophils 5.5 per cent, lymphocytes 0.5 per cent, and hemohistiocytes 0.5 per cent. The platelets were increased. Beginning on January 15, the patient received 48 Gm NaPAB daily for three days and 24 Gm daily thereafter. The dosage was decreased because the blood levels attained on 48 Gm a day ranged from 56 mg per cent to more than 70 mg per cent. By February 2, the white cell count had fallen to 60,000 per cu mm and the spleen was slightly smaller and considerably softer than on admission. There was a gain of four pounds. However, the hemoglobin level had fallen to 4.4 Gm. A blood transfusion was started on February 3. After receiving about 100 cc of blood, the patient com-

per cent, segmented neutrophils 26.5 per cent, eosinophils 6 per cent, basophils 4 per cent, and lymphocytes 1.5 per cent. The bone marrow was highly cellular with a great increase in granulocyte forms and reduction of erythropoietic elements. Urine analysis was negative. His fasting blood sugar was 47 mg per cent. Beginning on February 6, the patient received 48 Gm of NaPAB daily for three weeks when the dosage was decreased to 26 Gm per day and the patient was discharged. The leukocyte count decreased from 140,000 per cu mm on February 6 to 20,500 on February 27, and the hemoglobin fell from 10.8 Gm to 8.5 Gm. Fasting blood sugar level was 71 mg per cent on February 25. Glycosuria of 2 to 3 plus was present throughout the period of NaPAB administration. Twelve days later the white count was 22,500 per cu mm, and the hemoglobin had risen to 10.1 Gm. Despite 26 Gm daily of NaPAB, the patient's leukocytes began to increase gradually. On March 21 they numbered 49,750 per cu mm and the amount of NaPAB was raised to 40 Gm daily. A week later the white count was 87,000 per cu mm, but on the following week it had fallen to 47,000 per cu mm. The patient continued to take 40 Gm daily until April 4, when nausea and vomiting forced him to discontinue the medication. When seen again on April 8, the leukocyte count was 46,500 per cu mm, and the urine was free of glucose. By April 23 the white cells had risen to 125,740 per cu mm with a differential count similar to that at the onset of NaPAB therapy. Altogether, this patient received 2,134 Gm of NaPAB over a period of fifty-eight days.

Case 5. R. M. was a 71 year old white farmer who was well except for mild symptoms of prostatism until September, 1945, when he became aware of a growing mass in the left upper quadrant of the abdomen. Symptoms of anemia developed and he was admitted to the University Hospital in April, 1946, where the spleen was found to be much enlarged, extending below the level of the umbilicus. The hemoglobin value was 11.6 Gm per 100 cc and leukocytes numbered 75,000 per cu mm. The differential count was typical of chronic myelogenous leukemia. The patient received x-ray therapy to the spleen with subsequent improvement in his general condition and decrease in the size of the spleen. In October, 1946, his spleen appeared to be enlarging and he was bothered by a sense of fullness in the abdomen. On March 27, 1947, he was admitted to the Simpson Memorial Institute. At this time the liver descended 5 cm below the costal margin, and the spleen extended to 6 cm below the level of the umbilicus.

Repeated urine analyses were negative. The urea clearance test showed 71 per cent of normal in the first hour, and 63 per cent in the second hour. Blood urea nitrogen was 18.0 mg per cent and the nonprotein nitrogen was 42.6 mg per cent. The bromsulfalein test for liver function revealed only slight retention of the dye after forty-five minutes. An oral glucose tolerance test was performed after a three day preparatory high carbohydrate diet. The patient received 1.75 Gm of glucose per kilogram of ideal body weight. The results of this test in milligrams of glucose per 100 cc of blood were as follows: Fasting, 68, $\frac{1}{2}$ hour after glucose administration, 77, 1 hour, 88, $1\frac{1}{2}$ hours, 117, 2 hours, 103, $2\frac{1}{2}$ hours, 104, 3 hours, 104, 4 hours, 37, 5 hours, 53. There was 1 plus glycosuria in the second and third hourly specimens, but none at 1 hour, or at the fourth and fifth hours.

NaPAB was administered in dosage of 48 Gm daily, beginning on March 29, 1947. Before treatment the erythrocytes numbered 4,400,000 and leukocytes 94,500 per cu mm. The hemoglobin value was 13.0 Gm per 100 cc. The white blood cell differential count revealed blasts 2.5 per cent, promyelocytes 5.0 per cent, myelocytes 10.0 per cent, metamyelocytes 8.5 per cent, band neutrophils 21.0 per cent, segmented neutrophils 13.0 per cent, eosinophils 20.5 per cent, lymphocytes 1.5 per cent, hemohistiocytes 1.5 per cent, and basophils 6.5 per cent. Glycosuria appeared the day after the NaPAB therapy was started, and persisted throughout the period of treatment.

On April 9, 1947, the oral glucose tolerance test was repeated. Conditions of the test were similar to those before, with the exception that he was now receiving 4 Gm of NaPAB every two hours, and this was continued throughout the test period as well. The fasting blood sugar level was 56 mg per cent, $\frac{1}{2}$ hour, 78, 1 hour, 111, $1\frac{1}{2}$ hours, 120, 2 hours, 130, $2\frac{1}{2}$ hours, 133, 3 hours, 81, 4 hours, 80, 5 hours, 84. There was 2 plus glycosuria before glucose administration, and at the second, third, and fifth hours.

A urea clearance test on April 8, 1947, showed 85 per cent of normal in both the first and second hours. The bromsulfalein test was also repeated at this time, and showed no increased retention of the dye.

By April 12, the patient's leukocyte count had declined to 38,250 per cu mm, and the hemoglobin level had fallen to 9.1 Gm. The differential count was not significantly altered from that at the beginning of therapy. He was discharged on this date to continue NaPAB therapy at home. While in the hospital the patient received 712 Gm of NaPAB over sixteen days. He did not return for his scheduled follow up examination so that additional data are not available.

Case 6 L B The patient was a 66 year old housewife who noted weakness, weight loss, and anorexia beginning in March, 1946. The following month she developed furuncle-like skin lesions over face, neck, and chest. For six years she had had episodes of abdominal distress. She was admitted to the Simpson Memorial Institute on August 17, 1946. There was evidence of chronic illness and pallor. Moderately enlarged firm nodes were present in the neck and axillae. The spleen extended 4 cm below the left costal margin and the liver was felt 5 cm below the right lower rib margin. The hemoglobin was 5.6 Gm per 100 cc, and the white blood cells numbered 20,350 per cu mm. Differential count revealed many poorly differentiated cells including 46 per cent blast forms. There were 10 nucleated red blood cells per 100 leukocytes. The red cells were bizarre in form and size. Sternal marrow aspiration showed pronounced abnormalities of both erythropoiesis and granulopoiesis. A diagnosis of subacute myelogenous leukemia was made with the subclassification of erythroleukemia. Folic acid, 10 mg daily, was given for two weeks without any definite effect. On September 4, 1946, the white blood cell count was 23,000 per cu mm, and the hemoglobin level was 6.7 Gm. The differential count revealed myeloblasts 14 per cent, promyelocytes 19 per cent, myelocytes 18 per cent, metamyelocytes 17 per cent, neutrophil band forms 20 per cent, segmented forms 8 per cent, hemohistiocytes 2 per cent, and lymphocytes 2 per cent. On September 5, 1946, NaPAB was started in dosage of 24 Gm daily. Glycosuria was first noted on the day the drug was started and persisted while the medication was continued. Red cell values fell during the period of therapy and two transfusions were given. The drug was discontinued on September 20 after a total of 249 Gm had been taken. Blood values on that day were as follows: erythrocytes 2,300,000 per cu mm, leukocytes 13,000 per cu mm, hemoglobin 5.3 Gm, hematocrit 21.0 per cent, differential count: blasts 14 per cent, promyelocytes 8 per cent, myelocytes 35 per cent, metamyelocytes 20 per cent, band neutrophils 15 per cent, segmented neutrophils 4 per cent, lymphocytes 3 per cent, and hemohistiocytes 1 per cent. By September 25, the white cell count had risen to 43,000 per cu mm. The patient was discharged and died at home a few weeks later.

Case 7 A C This patient was a 43 year old Mexican building laborer who noted ease of fatigue in June, 1946. He was able to continue working until October, 1946, when he began to have episodes of vomiting and abdominal pain. About a month later he developed yellowish pallor, progressive symptoms of anemia, and gingival bleeding. He was admitted to the University Hospital on December 6, 1946. The patient was extremely pale, with a sallow skin color but no icterus of the sclerae. There were a few small nodes in the neck and axillae, the liver was felt 3 cm below the costal margin, and the spleen could not be palpated. On December 12, the patient was transferred to the Simpson Memorial Institute where a diagnosis of subacute subleukemic myelogenous leukemia was made. Marrow examination of this patient revealed extensive involvement of the erythropoietic as well as the granulopoietic series, and so led to the secondary diagnosis of erythroleukemia as in the preceding case.

Blood values were as follows: Erythrocytes 2,300,000 per cu mm, leukocytes 8,000 per cu mm, hemoglobin 6.6 Gm per 100 cc, hematocrit 22.0 per cent, mean corpuscular volume 96 cu microns, differential count: myeloblasts 5 per cent, promyelocytes 2 per cent, myelocytes 2 per cent, neutrophils 54 per cent, eosinophils 1 per cent, lymphocytes 35 per cent, hemohistiocytes 1 per cent. There were 20 nucleated erythrocyte elements per each 100 leukocytes counted. Urine analysis was negative. The fasting blood sugar level on December 16 was 71 mg per cent. On that day, NaPAB was begun in a dosage of 48 Gm daily. On the following day glycosuria appeared and continued during the period of NaPAB therapy. The fasting blood sugar level was 61 mg per cent on January 6. The white blood cell count varied considerably, but tended to decrease during the second week of therapy to levels between 2,000 and 3,000 per cu mm which were maintained until the NaPAB was discontinued on January 28. On January 14 the patient developed indurated furuncle-like lesions on the thighs. Three of these enlarged and ulcerated. Secondary infection occurred and the lesions remained stationary as large shallow ulcers. Three 500 cc blood transfusions were given during the NaPAB therapy. Blood values on January 27 were as follows: Erythrocytes 2,000,000, leukocytes 1,800 per cu mm, hemoglobin 5.0 Gm per 100 cc, hematocrit 18.0 per cent, mean corpuscular volume 90 cu microns. The differential count was essentially unchanged from the pretreatment values, except for a relative increase in blast forms.

A series of blood transfusions were given during the following week and the hemoglobin was raised to 12.5 Gm. The white blood cell count increased slightly and was 4,000 per cu mm on February 16 when the patient was discharged. Before discharge, a course of x-ray therapy was given to the ulcers on the lower extremities.

The patient returned on February 26. At this time there had been some improvement in the ulcerating lesions on the legs. The hemoglobin had fallen to 10.3 Gm, while the white cell count had risen to 17,300 per cu mm. There was a striking change in the differential which showed 85 per cent myeloblasts and only 1 per cent mature neutrophils. Late in March the patient was readmitted for a series of plasma transfusions during which the white cells continued to increase in number, reaching 58,500 per cu mm with 71 per cent myeloblasts and 15 per cent mature neutrophils.

A glucose tolerance test was performed on April 9. The fasting blood sugar level was 67 mg per cent. The blood sugar levels of specimens taken at test intervals were as follows: $\frac{1}{2}$ hour, 130, 1 hour, 236, $1\frac{1}{2}$ hours, 284, 2 hours, 240, $2\frac{1}{2}$ hours, 162, 3 hours, 120, 4 hours, 56, and 5 hours, 50. The fasting urine specimen was negative for glucose as were those obtained at 1, 3, 4, and 5 hours. Only the specimen collected at $2\frac{1}{2}$ hours gave a reaction (3 plus) for glucose. On April 11, NaPAB therapy was reinstituted in a daily dose of 48 Gm for nine days, when it was discontinued because of nausea and cramping abdominal pain. Glycosuria was again noted during the NaPAB treatment, but disappeared four days after cessation of therapy. The white cell count showed no distinct change during the period of therapy, but during the next nine days it rose from 42,250 to 74,000 per cu mm.

Case 8 L. D. The patient was a 38 year old white tool grinder who was first seen at the University Hospital in September, 1945, for low back pain of seven years duration. A diagnosis of spondylitis rhizomelique was made and the patient later received a course of x-ray therapy to the spine at another hospital. In October, 1946, he developed symptoms of anemia which became progressively more severe. He was admitted to University Hospital on December 20, 1946. Examination revealed extreme pallor. Lymph nodes were not enlarged and the spleen was not palpable. On the basis of laboratory findings a diagnosis of subacute myelogenous leukemia was made and the patient was given three transfusions, each of 500 cc whole blood. On December 26, the patient was transferred to the Simpson Memorial Institute. At that time blood values were as follows: Red blood cells 2,300,000, white blood cells 41,500 per cu mm, hemoglobin 7.8 Gm per 100 cc, hematocrit 22.0 per cent, differential count: myeloblasts 22 per cent, promyelocytes 2 per cent, myelocytes 18 per cent, metamyelocytes 23 per cent, band neutrophils 4 per cent, segmented neutrophils 5 per cent, eosinophilic myelocytes 9 per cent, eosinophilic metamyelocytes 9 per cent, lymphocytes 7 per cent, and hemohistiocytes 1 per cent. The fasting blood sugar level was 81 mg per cent. Administration of NaPAB was begun on December 28, the patient receiving 48 Gm daily. On the following day glycosuria was noted and this persisted throughout the NaPAB therapy. During the second week of treatment the white count began to fall and by January 11, 1947, had reached 8,300 per cu mm. On January 11, NaPAB was discontinued and on January 14, it was resumed but the dosage was decreased to 24 Gm daily. Six more blood transfusions were given during the period of therapy with NaPAB. On February 1, 1947, the blood values were as follows: Erythrocytes 3,500,000 per cu mm, leukocytes 2,200 per cu mm, hemoglobin 10.2 gm, hematocrit 33.0 per cent, differential count: myeloblasts 23 per cent, promyelocytes 2 per cent, myelocytes 8 per cent, metamyelocytes 8 per cent, band neutrophils 21 per cent, segmented neutrophils 21 per cent, lymphocytes 12 per cent, and hemohistiocytes 5 per cent. At this time the NaPAB was discontinued and the patient was discharged. He had received 1,230 Gm of NaPAB over thirty four days. He died at home about two months later.

Case 9 C. K. This patient was a 68 year old white highway construction foreman who had had excellent health until August, 1946, when he developed vague discomfort in the upper abdomen often occurring two or three hours after meals. The following month he lost a considerable amount of weight although his appetite remained normal. In December, symptoms of anemia became prominent and progressed until his admission to the Simpson Memorial Institute on February 3, 1947. Mild symptoms of hypermetabolism had been noted during the three months before admission. Examination revealed extreme pallor, generalized lymphadenopathy, hepatomegaly and splenomegaly. Blood values were as follows: Hemoglobin 4.3 Gm per 100 cc, red blood cells 1,600,000, white blood cells 252,000 per cu mm, red cell packed volume 14.0 per cent, white cell packed volume 5.0 per cent, differential count: atypical lymphoid cells 99 per cent, some with notched nuclei, and polymorphonuclear neutrophils 1 per cent. Sternal marrow aspiration revealed almost complete replacement by the abnormal lymphoid forms. Serum bilirubin was 0.65 mg per cent. On February 6, 1947, NaPAB, 48 Gm daily, was started. On February 17, the white cell count had fallen to 101,750 per cu mm. On February 19, a differential count showed no granulocyte forms except for 1 eosinophil in several hundred cells observed. On February 19, the patient had a sudden onset of chills, fever, and cough and NaPAB was discontinued. He had received 634.0 Gm over fourteen

days. In spite of penicillin therapy and supportive measures, the patient died on February 21. On the day before death, the white count had risen to 180,500 per cu mm. Two plus to 3 plus glycosuria was present during the NaPAB therapy. Autopsy permission was obtained and the pathologic diagnosis was lymphoblastoma of lymphatic leukemia type.

Case 10. R. W. This patient was a 77 year old retired white business man who developed an upper respiratory infection late in December, 1946. Early in January he began to notice weakness and malaise and complained of persistence of nasal discharge and a full feeling in his head. A blood count was done and because of the abnormal white count the patient was admitted to the Simpson Memorial Institute on February 25. He appeared much younger than his age, but was definitely pale. There were a few small soft lymph nodes palpable in the neck and axillary regions. The spleen was greatly enlarged, extending 7 cm. below the level of the umbilicus. Blood values were as follows: Red blood cells 2,700,000, white blood cells 410,500 per cu mm, hemoglobin 7.1 gm. per 100 cc, hematocrit 24.0 per cent, differential count: neutrophils 3 per cent, eosinophils 0.5 per cent, monocytes 0.5 per cent, atypical lymphocytes 96 per cent. Sternal marrow aspiration revealed almost complete replacement by the abnormal cells of the type seen in the peripheral blood. The diagnosis was chronic lymphatic leukemia of an atypical type. NaPAB was started on March 1 in dosage of 48 Gm. daily. On March 4, the dose was reduced to 24 Gm. daily. Glycosuria occurred, usually of two plus degree. On March 12, 1947, auricular fibrillation was noted and digitalis was given. On March 13, the patient received a transfusion of 500 cc. of blood. The NaPAB was discontinued on March 19, 1947, because of nausea, temperature elevation to 101 F., and apparent decrease in the granulocytes of the peripheral blood. The blood values on that day were: Leukocytes 352,500 per cu mm, hemoglobin 6.6 Gm., differential count: neutrophils, less than 0.1 per cent, eosinophils 0.5 per cent, and abnormal lymphocytes 99 per cent plus. On March 22 the white blood cells had increased to 528,500 per cu mm. During the following week the patient was given a course of nitrogen mustard therapy (methyl-bis (beta-chloroethyl) amine). On April 7, the white cell count had fallen to 133,000 per cu mm, and there were 4.5 per cent neutrophils.

DISCUSSION

From the foregoing case reports, it is evident that para-aminobenzoic acid administered in large doses as sodium para-aminobenzoate will bring about a decline in the total leukocyte count of patients with chronic myelogenous leukemia. The fall in white count usually begins during the latter half of the second week of therapy and is most precipitous during the third week. When NaPAB therapy is discontinued, the leukocyte count begins to rise within a few days. Reinstitution of NaPAB administration will again cause a fall in the leukocyte count.

One patient with subacute myelogenous leukemia showed an appreciable fall in the leukocyte count while receiving NaPAB, but little could be evaluated from the results of the administration of NaPAB to the other two patients with subacute myelogenous leukemia of erythroleukemic type.

NaPAB administration was followed by slight decreases in the cell counts of the two patients with lymphatic leukemia, but in these cases therapy was maintained for only fourteen and nineteen days, respectively. It was discontinued primarily because of nausea in one instance, and signs of infection in the other. Both patients then had sharp increases in their leukocyte counts, which were interpreted as evidence that NaPAB had been exerting an effect on the white blood cell level.

Para-aminobenzoic acid in sufficiently high concentration appears to inhibit all phases of granulocyte development in chronic myelogenous leukemia. There was no consistent change in the differential counts of patients receiving this compound and studies of sternal marrow specimens have failed to reveal any blockage phenome-

non '' However, after the first week of treatment, a striking vacuolation of the cytoplasm developed in the myeloblasts and promyelocytes. This change is illustrated in figures 1 and 2 prepared from material obtained by sternal aspiration from patient 3. Figure 1 pictures the marrow prior to the institution of treatment, while figure 2 is of material secured on the thirty-fifth day of NaPAB therapy.

In three of the patients with chronic myelogenous leukemia treated with NaPAB, there was a temporary improvement in the hemoglobin value and the erythrocyte count. There was no apparent effect on the platelets.

FIG 1 Bone marrow film from patient 3 before treatment showing relative increase in granulocyte forms

Clinically, the patients were not substantially benefitted by the administration of NaPAB. In some instances the spleen decreased in size, the patients gained weight, and there was a diminution of the symptoms of hypermetabolism. However, these effects were not long maintained after the NaPAB was discontinued. In other patients, there was no objective clinical improvement. Three of the patients died in the hospital, and postmortem examination was performed on one (Case 9). The pathologic findings in this case were largely those of the leukemic process. There were no apparent deleterious effects of the NaPAB.

Although the mechanism of action whereby NaPAB in high concentration disturbs leukocyte proliferation and development is not understood, it appears that the factors which cause and maintain elevated leukocyte counts in leukemia are

merely inhibited by NaPAB. The possibility that there is an accumulation of these factors during the period of NaPAB administration is suggested by the striking increase in the number of white cells following the cessation of therapy, and by the more gradual leukocyte increases in patients maintained on reduced dosages of NaPAB (charts 3 and 4).

It is also of interest that glycosuria appeared in all of the patients who received NaPAB. A "reducing substance" was noted in the urines of NaPAB treated patients by the U. S. A. Typhus Commission workers⁷ but the nature of this substance was

FIG. 2. Bone marrow film from patient 3 after thirty five days of NaPAB therapy. Myeloblasts and promyelocytes show vacuolation of the cytoplasm. The apparent increase in immature cell forms is the result of field selection for demonstration of the vacuoles.

not investigated. Our studies have shown that the reduction of Benedict's solution is caused by glucose, as determined by characteristic osazone reactions. Glucose usually appears in the urine within twenty-four hours after the administration of NaPAB is begun and persists for one to four days after it is discontinued. In a few quantitative determinations, the amounts of glucose excreted ranged from 5.0 Gm to 17.5 Gm per twenty-four hours.

The basis for glycosuria during NaPAB therapy is being further investigated. Fasting blood sugar levels taken before and during therapy have shown no significant differences. Glucose tolerance studies in two of the patients revealed that the pretreatment renal thresholds for glucose were considerably higher than the

level at which excretion occurred while NaPAB was being taken. These observations indicate that the glycosuria is on a renal basis. It does not seem likely that a simple competition phenomenon accounts for the glycosuria and it may be that NaPAB interference with the renal phosphorylation mechanism is the true explanation.

SUMMARY AND CONCLUSIONS

Para-aminobenzoic acid, administered in large doses as sodium para-aminobenzoate caused a striking lowering of the leukocyte counts in five patients with chronic myelogenous leukemia and in one patient with subacute myelogenous leukemia.

NaPAB caused less definite decreases of the white cell count in two patients with chronic lymphatic leukemia, but the periods of administration may have been too short to obtain maximal effects.

In every instance, there was a prompt rise in the number of leukocytes when the administration of NaPAB was stopped.

Although there was decrease in spleen size in some of the patients, the objective clinical improvement was but slight and temporary.

All patients receiving NaPAB in large doses had concomitant glycosuria, apparently on a renal basis.

It is to be emphasized that NaPAB is not considered a practical adjunct to the therapy of leukemia at this time. Rather, it is hoped that studies of the cellular chemistry involved in the apparent inhibitory action of NaPAB may yield information concerning the disordered metabolism of leukemic cells.

ACUTE THROMBOCYTOPENIA INDUCED IN DOGS BY ADMINISTRATION OF URETHANE (ETHYLCARBAMATE)

By W O CRUZ, M D ,* AND H MOUSSATCHÉ, M D

THE SUBSTANCES inducing thrombocytopenia can be divided into two categories those which act exclusively on the platelets and those which, in addition to this action, act also on the leukocytes and red blood cells

True thrombocytopenia, with no alteration of leukocytes and red blood cells, has been described in man as caused by the administration of organic substances, such as arsenic salts (arsphenamine, neoarsphenamine, etc), gold salts, and benzene Physical agents, such as x-rays and emanations of radioactive substances, cause thrombocytopenia, always accompanied, however, by leukopenia and anemia

Descriptions have already been made of experimental thrombocytopenia and anemia in dogs, induced by the administration of estradiol benzoate in heavy doses and by injection of antiplatelet serum In previous publications,¹⁻⁵ one of us (W O C) has studied the relation between the decrease of the number of circulating platelets and the occurrence of anemia

This article describes the thrombocytopenic action of ethylic urethane administered to dogs in heavy doses Other blood changes resulting from urethane administration are also described

METHODS

The volume of the platelets was determined by the Van Allen thrombocytocrit and the results were expressed in ml platelets per 100 ml of blood Details of the hematologic technic used for leukocyte and red blood cell counts are described in a previous paper ⁶ Urethane was used in a 60 per cent solution in distilled water

EXPERIMENTAL RESULTS

Preliminary trials with various dosages and routes indicated that the drug exerted some effect on the platelets

Dog 393, 8 Kg

Day of Experiment	Leukocytes 10 ³ /mm ³	Platelets ml / 100ml blood	Observations
0	10 4		Daily administration of 3 Gm of urethane (0 38 Gm p/Kg) by mouth
2	17 8	0 58	
5	28 4		
8	16 0	0 40	
12	12 2		Administration of urethane by mouth discontinued
30	2 0		
34			Administration of the same dose of urethane subcutaneously
36	7 8	0 11	Killed by injection of air intravenously Post-mortem examination Hemorrhages in the epiploon and mediastinum No lesions in intestine

From Instituto Oswaldo Cruz, Rio de Janeiro, Brazil

* Aided by a grant from Dr Guilherme Guinle

Dog 392, 7.8 Kg

<i>Day of Experiment</i>	<i>Leukocytes 10³/mm³</i>	<i>Platelets ml / 100ml blood</i>	<i>Observations</i>
0	17.2		Daily subcutaneous injection of 3 Gm of urethane (0.38 Gm p/Kg)
1	31.2		
3	22.0		
8	16.4		Injection area swollen, sensitive to touch, hindering the animal's walk
10	6.4	0	Purpura in areas of injection and other regions of the skin Red blood cells, $4.2 \times 10^6/\text{mm}^3$ Hemoglobin, 10.8 Gm 100 ml of blood Hematocrit, 33%
11	2.2		
12			Found dead in the morning Postmortem examination Medium sized petechiae throughout the intestine, with no preferential zone Profuse hemorrhage in injection site

Dog 5, 6.2 Kg, Male

Daily subcutaneous injection (0.1 Gm per Kg) for twenty-two days. On thirteenth day, hemorrhagic zone was noted in inguinal region around one of injection areas, hematologic data showed 6,200 leukocytes per mm³ and 0.10 ml platelets/100 ml blood. The purpura receded and no hemorrhagic spots were observed.

On the twenty-third day of experiment, urethane was increased to 0.4 Gm per Kg.

On the twenty-eighth day of experiment, cutaneous petechiae were observed.

On the thirtieth day, the animal was killed, after verification of lack of platelets in circulation. Postmortem examination showed presence of many isolated hemorrhagic points throughout the intestine. Hemorrhage in intestinal lumen. Petechiae in both lungs, epiploon and hemorrhage in perirenal tissue.

Dog 7, 5.4 Kg

Daily subcutaneous injection of urethane (0.4 Gm p/Kg) for nine days. On ninth day, petechiae on skin of abdomen. On tenth day, hematologic data showed Red blood cells 1,100,000 mm³.

Hemoglobin, 2 Gm /100 ml blood. Hematocrit, 8 per cent. White blood cells, 3,000 ml. Platelets, 0. Animal killed. Autopsy showed in the intestine typical picture of hemorrhagic purpura. Pulmonary petechiae.

Three other animals received subcutaneously urethane in doses of 0.4 Gm /Kg body weight for nine days, 0.2 Gm /Kg for eighteen days and 0.4 Gm /Kg for twelve days. They all died and showed little or no purpura. These preliminary observations led us to try experiments which would show more adequately the hematologic changes of thrombocytopenic purpura. Results are given in table 1.

DISCUSSION

The thrombocytopenic action of urethane has not been previously described. The results referred to above show that this substance has an acute thrombocytopenic action when given to dogs in sufficient quantity subcutaneously. Urethane apparently does not act specifically on platelets, but on all the cell elements of the blood. Leukopenia was also observed in the final phase, and acute anemia without regenerative phenomena, in addition, the platelets disappeared completely from the circulation. The sequence of this picture is similar to that observed when heavy doses of estradiol benzoate are administered to dogs: initial leukocytosis, disappearance of platelets, and finally acute anemia. The animal

treated with urethane present a leukopenia which may attain extremely low values in the final phase of the picture

The fall of red blood cells coincides with the appearance of severe intestinal hemorrhages as a consequence of purpuric lesions in the mucosa of the small

intestine (figs. 1 and 2). Purpuric lesions similar to those observed in the intestine are frequently found in the lung, cortical zone of kidney, heart, perirenal tissue, epiploon, and skin.

We call attention to the fact that the picture of purpura is established even

when the administration of urethane is discontinued after the fall in the number of platelets. This was the case in dogs 409-3 and 411-6, where the administration of urethane was discontinued on the eighth day of the experiment but the blood changes continued to develop until the final stage, as can be seen in table 1.

The dose of urethane used in the animals listed in table 1 (0.4 Gm per Kg) may approach a dose which would intoxicate the animal prior to the appearance of purpura, this might explain the premature death of two dogs (3 and 407-1).

FIG. 1. Dog 409-3

Digestive tract showing extensive purpuric lesions in the small intestine, especially in the jejunum. Stomach, duodenum, and large intestine free of lesions.

The administration of a smaller dose of urethane (0.2 Gm per Kg) for eighteen days did not reveal the typical picture of fulminating purpura. Administration by mouth (0.4 Gm per Kg) for thirty-six days in dog 393 did not produce purpura.

It would still be necessary to discover whether the urethane action is specific for dogs, as is the case with estradiol benzoate. In support of this idea is the fact that urethane was administered to many other species without producing a picture similar to that here reported.

With regard to the mechanism of urethane purpura, it would be well to remember the studies of Krogh⁶ and co-workers on the action of urethane on the capillaries. This author, by microscopic observation, verified an intensive dilatation of

capillary vessels of the tongue of frogs submitted to the action of urethane. Also, Landis⁸ observed, by introduction of a micropipet in a capillary, an increase of the capillary pressure and permeability in these animals. In the cases of intoxication with high doses of urethane, the capillary pressure may attain values close to arteriolar pressure, the increase in permeability would be connected with the toxic action of the urethane on the capillary wall. It may be supposed that the rupture of the capillary results from damage of the capillary wall combined with

FIG. 2. Dog 411-6

Extensive purpuric lesions in the small intestine, especially in the jejunum

the increase of capillary pressure. Rupture of capillaries was observed by Doljanski and Rosin⁹ in studies made on the effects of urethane on the sinusoid capillaries of rat livers.

The known toxicity of urethane for the capillaries and its capacity for inducing purpura could be interpreted as facts in support of the hypothesis of Bedson¹⁰ and others that the primary cause of purpura lies in a change in the capillary endothelium, and not in the thrombocytopenia. However, disappearance of the platelets of the circulating blood some days before the occurrence of purpura in the animals treated with urethane, or, as was shown in previous observations, in animals treated with estradiol benzoate, indicates that the platelets are involved in the mechanism of purpura.

It has not been possible to the present time to determine the primary cause in

the mechanism of urethane purpura, but it seems to us that the whole question of purpura could be attacked with advantage by the use of urethane. Water solubility, low price, as well as easy commercial availability are some of its advantages over estradiol benzoate and antiplatelet serum for the study of experimental purpura.

Because of its leukopenic action, urethane administered by mouth has been used recently¹¹ in the therapeutic of leukemias. Despite the fact that it is necessary to administer higher doses to dogs than those administered to patients with leukemia, and taking into consideration the fact that subcutaneous injections were used in dogs, it appears to us that in patients treated with urethane it would be advisable to determine periodically the number of circulating platelets.

SUMMARY

1. Dogs treated for one to two weeks with daily injections of urethane (ethyl carbamate) subcutaneously, in doses of 0.4 Gm per Kg of body weight, presented a typical picture of thrombocytopenic purpura.

2. The pathologic changes consisted in numerous purpuric lesions in the small intestine and a smaller number on the skin, heart, lung, cortical zone of the kidney, epiploon, and, rarely, on the stomach and large intestine.

3. The hematologic changes occurred in the following sequence: leukocytosis, leukopenia and thrombocytopenia, and finally acute anemia coinciding with severe intestinal hemorrhage. In the final phase, the coagulation time was normal and the bleeding time very much increased.

A METHOD FOR OBTAINING LIVING LEUKOCYTES FROM HUMAN PERIPHERAL BLOOD BY ACCELERATION OF ERYTHROCYTE SEDIMENTATION

B₃ ALLEN H MINOR,* M D , AND LEE BURNETT, M S

IN OBTAINING leukocytes from human peripheral blood, use has been made of a physiologic mechanism for accelerating erythrocyte sedimentation. Gray and Mitchell¹ found that the addition of fibrinogen in adequate amounts to heparinized blood causes the red cells to settle so rapidly that they approach cell volume at the end of one hour. We have noted that at one hour, in blood exhibiting an accelerated erythrocyte sedimentation rate, approximately the same concentration of leukocytes remains in the plasma overlying the red cells as is found in capillary blood, and that the differential counts are similar. These leukocytes are alive. Data are presented which show that fibrinogen added to heparinized blood permits the recovery of living leukocytes suspended in their own plasma. This recovery is attended by a minimum of technical difficulty, of physical traumatization, and of erythrocyte admixture.

METHOD

Reagents

1. Heparin, 100 mg per cent solution, made up in isotonic saline. This solution may be kept in a stoppered bottle at room temperature for several months without significant loss of activity.
2. Fibrinogen solution. This is made up fresh daily by dissolving 310 mg of Fraction I from bovine plasma (Armour) in 10 ml of distilled water. This solution contains approximately 20 mg of fibrinogen per 1.25 ml. Brief incubation at 37 C facilitates solution.

Procedure

- All glassware and needles must be clean and dry.
1. Into a 15 ml tube, pipet 0.4 ml heparin solution.
2. Into a syringe, aspirate rapidly but not forcibly 10 ml of venous blood. Remove the needle and transfer the blood into the tube.
3. Add 1.25 ml fibrinogen solution and mix by inversion.
4. Into another 15 ml tube, pipet 10 ml of this mixture, taking care that the glass above the fluid remains clean, stopper the tube.
5. Slant the tube at a 60 degree angle and incubate at 37 C.
6. After one hour, remove the tube from the incubator and introduce the tip of a 2 ml pipet about 2 cm below the meniscus of the supernatant fluid, taking care not to agitate the erythrocytes.
7. Transfer 2 ml of this fluid to another container. This is a plasma suspension of living leukocytes.

DATA

Table 1 shows total and differential leukocyte counts and total erythrocyte counts on capillary blood, and on plasma suspension of leukocytes obtained by the method given. Uncorrected erythrocyte sedimentation rates on heparinized venous bloods, determined with Wintrobe tubes at room temperature, are also shown. Data are

From the Sloan-Kettering Institute for Cancer Research, New York, N. Y.

* Trainee, National Cancer Institute

given for consecutive blood examinations of twenty normal individuals (blood donors)

This table shows that after acceleration of the normal erythrocyte sedimentation rate a suspension of leukocytes is obtained in which the concentration and distribution are similar to that found in capillary blood. It also shows that an average clearance of 99.8 per cent of erythrocytes is effected in the suspension. The majority of the residual erythrocytes are present as rouleaux of from five to twenty cells, and

only very occasional thrombocytes are found in fresh preparations or stained smears of suspension.* Consequently, in many fields observed with high magnification, only leukocytes are seen.

Figures 1 and 2 are photomicrographs, taken two minutes apart, of a drop of suspension obtained by the method given from a normal individual. The changes in

* This is true because the thrombocytes are for the most part suspended just beneath the cover slip, or are adherent to it, and hence are not in focus while viewing the underlying blood cells. Platelet counts on capillary blood and suspension show a reduction of about 50 per cent in platelet concentration in the suspension.

FIG 1 GRANULAR LEUKOCYTES SUSPENDED IN THEIR PLASMA, RECOVERED FROM NORMAL HUMAN PERIPHERAL BLOOD BY ACCELERATION OF ERYTHROCYTE SEDIMENTATION ($\times 610$) DARK-FIELD ILLUMINATION

FIG 2 SAME FIELD AND MAGNIFICATION AS FIG 1, TWO MINUTES LATER. Note changes in shape and

shape and position of these granular leukocytes, in conjunction with their undiminished refractility as observed with dark-field illumination, afford proof of their vitality

DISCUSSION

The method given for leukocyte recovery is technically simple. The two reagents used are readily available, no special apparatus is needed, working time is measured in minutes. Minor modifications of the conditions recommended will yield satisfactory results. erythrocyte sedimentation may be carried out at room temperature or with the tube upright, and the sedimenting time is not critical. We have observed, however, that the concentration of fibrinogen salt solution cannot be increased without significant impairment of the vitality of granular leukocytes.

There is minimal traumatization to the leukocytes. The reagents used are substances normally encountered physiologically. Normally circulating leukocytes are obtained, rather than cells accumulating in response to an inflammatory stimulus.

The procedure is applicable to large or small quantities of blood, it has been used successfully with 500 ml. and 1 ml. volumes.

It should be readily adaptable to anaerobic or aseptic technique.

SUMMARY

A simple method for obtaining living leukocytes from human peripheral blood is presented. It consists of the addition of fibrinogen to heparinized blood. Essentially all the leukocytes remain in plasma suspension and essentially all the erythrocytes are sedimented out at the end of one hour.

ACKNOWLEDGMENT

The authors wish to express their thanks to Miss Alma Manieri, who did all the blood counts for this study, and to Mr. Antol Herskovitz, who prepared the photomicrographs.

EDITORIAL

"SHOT-GUNS"

THE popularity of the numerous and varied shot-gun preparations in the treatment of anemia is one of the features of modern medical practice. Perhaps this points a moral.

Anemia is fundamentally a symptom, being indicative either of a deficiency state, a disturbance of the bone marrow, or of increased blood loss. Anemia per se should not be considered as a disease, and since it is always symptomatic or secondary of something gone wrong in the bodily economy, a thorough-going effort to determine its cause should always be made. The practice of giving mixtures of liver extract, folic acid, iron and vitamin B to patients with anemia in the hope that one or the other of these substances might hit the mark deserves critical comment. Not only is this method slipshod, but it is often wasteful of the patient's finances, and, indeed, in many instances is distinctly dangerous.

Since anemia, if it is actually present (frequently it is not), indicates some sort of abnormal state, it is of prime importance for the physician to attempt to discover the abnormality. This requires a careful history as regards dietary habits, gastrointestinal complaints, bleeding, chemical exposure, hereditary disease and the like. A careful physical examination, followed by an evaluation of the blood picture, will then usually lead to a fairly conclusive idea as to what type of anemia is present, and its possible etiologic mechanisms. A few other studies, including such procedures as stool examinations for occult blood, x-ray examinations, bilirubin estimations, studies of the aspirated bone marrow, etc., will usually lead to a final diagnosis. There can be no doubt that this procedure is time-consuming and requires considerably more trouble than prescribing one or the other shot-gun mixture. On the other hand, a careful study is valuable for the patient, informative for the physician and productive of knowledge which should be helpful in determining whether a simple medication or perhaps a radical surgical procedure is the treatment of choice in a given case.

The prescribing of multi-drug preparations is apt to be wasteful of the patient's finances, for usually some of the numerous medications contained in a given capsule or pill are completely unnecessary. If the patient has an iron deficiency, he needs iron in adequate amounts, not liver extract, not folic acid, not vitamin B complex and not vitamin C. The iron present in the preparation is perhaps adequate, but frequently it is not, and to obtain an optimum amount the patient must often take six to a dozen capsules. There is no good evidence indicating that liver and the various vitamins act as adjuvants to iron. On the other hand, they raise the cost of the preparation five- to twentyfold without otherwise performing a single useful function. Similarly, when a patient has pernicious anemia, what he needs is liver extract or folic acid in optimal amounts and not iron or vitamin B complex. The watchword should be specific medications for specific deficiencies. It may be stated parenthetically that none of the various antianemic preparations *stimulate*

blood formation There are *no* hematopoietic stimulants, only materials which supply a given deficiency, if it is present

Why then may the prescription of multidrug preparations be of distinct danger? Suppose, for example, that the patient has hypochromic anemia due to unrecognized chronic bleeding from the bowel, administration of a shot-gun preparation may well relieve the anemia, at least to some extent and for a little time, but meanwhile the neoplasm or other condition causing the bleeding may continue relentlessly and by the time it becomes obvious, radical surgery may be of no value Or suppose the patient has pernicious anemia and is given six pills or capsules daily containing a small amount of liver extract This amount may well initiate a minor therapeutic response, largely hematologic, but will hardly be sufficient to protect the patient against neurologic complications

Too many attractive preparations for the treatment of anemia are on the market Their worth to the practising physician and to the patient is often highly questionable There is need for cooperative action on all fronts so that the patient may be protected from useless, expensive, and potentially harmful medications This will require not only constant vigilance on the part of the physician but a highly developed ethical sense on the part of the pharmaceutical manufacturer as well as a firm determination on the part of the publisher of medical periodicals to accept only those advertisements which do not overstate the case for a given preparation Where to draw the line is sometimes difficult, but if any one of the groups concerned falters in its determination to give the patient the best possible chance, the shot-gun habit will continue, and will sooner or later back-fire Although a certain degree of financial sacrifice is bound to occur through well-controlled advertising selection, there can be no question that a frontal attack on this problem by practising physicians, pharmaceutical manufacturers and medical publishers would surely redound to the credit of all concerned and prove to be of great help to the ultimate consumer, the patient Through the cooperation of the publisher and the members of the editorial board, this Journal has been making efforts, oftentimes with great difficulty, to screen advertising copy very carefully It will continue to do so

RADIATION AND RADIOACTIVE ISOTOPES

MEDICAL APPLICATIONS OF ARTIFICIAL RADIOACTIVE ISOTOPES *K. A. Evelyn* From the Department of Medicine, McGill University, Montreal, Quebec, and the Hypertension Research Committee, Massachusetts General Hospital, Boston, Mass. *Canad. M. A. J.* 56: 547-554, 1947

The author presents a remarkably lucid review of some of the fundamental principles pertaining to the medical use of artificial radioactive isotopes. Definitions of the terms isotope, radioactivity, hard ray, soft ray and rate of disintegration will be particularly helpful to the uninitiated. The uses of the Lauritsen electroscope, Geiger counter and the radio-autograph technic are briefly explained. The present status of tracer research is summarized with especial reference to some of the technical difficulties involved. Characteristics of some of the more important artificial radio-elements are given in easily understood tabular form. Data are included on radio-hydrogen, -carbon, -oxygen and -nitrogen because of their potential value, despite the fact that various difficulties are delaying their widespread use.

Discussion of the use of artificial radio-elements for internal radiation therapy is largely confined to radio-phosphorus and radio-iodine. The health hazards involved in the use of artificial radioactive isotopes are properly emphasized.

L E Y

THE USE OF ISOTOPES IN MEDICAL RESEARCH *J. H. Lawrence* From the Donner Laboratory of Medical Physics, University of California, Berkeley, Calif. *J. A. M. A.* 134: 219-225, 1947

This report is a brief, lucid presentation of certain of the fundamental principles in the applications of isotopes in medical investigation and therapy. Isotopes are forms of a given element which have different atomic weights, certain isotopes not only have different weights, but also emit rays of various types, and are, therefore, known as radioactive isotopes. The amounts of such substances can be determined by means of the Geiger-Muller counter and similar devices. Artificially radioactive elements can be produced either by use of the cyclotron (which bombards given elements with positively charged nuclear particles) or by means of the uranium pile (which bombards elements with slow, uncharged neutrons). In general, such isotopes have two uses for medicine: (1) for therapeutic irradiation, and (2) for tracer studies of the metabolism of the particular element.

Lawrence tabulates a number of radioactive substances in use in research, and discusses three principal technics used in such studies: (1) In the *autoradiographic technic*, a tracer dose of a substance is given, tissues are sectioned at various intervals and placed against photographic film, these photographs are then examined to determine which organs have taken up the substance. (2) In the *in vitro technic*, a radioactive substance is given, and samples of blood, urine, etc., are taken at various intervals and measured for radioactivity. (3) In the *in vivo technic*, a Geiger counter is placed successively over various parts of the body after administration of a radioactive substance, and the uptake by various organs thus determined. Cobalt, for example, is taken up largely by the liver, and iodine by the thyroid gland.

This article is an excellent brief introduction to the methods and principles of radioactive research in medicine.

S E

THE HEMATOLOGICAL EFFECTS OF IONIZING RADIATIONS IN THE TOLERANCE RANGE *L. O. Jacobson and E. K. Marks* From the Metallurgical Laboratory, University of Chicago, Chicago, Illinois. *Radiology* 49: 286-298, 1947

The plutonium project was that section of the Manhattan District which had the specific task of preparing and purifying plutonium for use in atomic bombs, according to the general formula, $U^{235} + \text{neutron} = \text{chain reaction}$, which gives 1 neutron which bombards U^{238} (in the pile) to give plutonium. Studies of the physical, biologic, and clinical effects of irradiation were made throughout the work. It was the task of Jacobson and Marks to study the hematologic data in individuals exposed to irradiation within the 'permissible' or 'tolerance' range, i.e., up to 0.1 roentgens per day. Some of their results are summarized in this report.

Rabbits, mice, and guinea pigs were exposed to irradiations under conditions meant to duplicate the laboratory exposure which scientists and their assistants received in radiation laboratories. The animals were given whole body chronic exposure to external radiations, in various groups (0.1, 1, 2, 4, and 8.8 roentgens for eight to twenty-four hours daily, six days a week, for over three years). Tolerance doses (0.1 r/day) had no effect on the blood. Doses of 2.2 r/day or more resulted in changes in all 3 species, including lymphocytopenia (the earliest change), anemia, and, in the highest doses, death. No lymphocytosis, eosinophilia, or monocytosis occurred in any species at any dosage levels. It was of interest that, in female mice, ovarian tumors developed in doses of even 0.1 to 1.4 r/day, i.e., *in the absence of hematologic changes*.

The hematopoietic system of man was found to have the same sensitivity to irradiation as that of the guinea pig and the dog. When exposed to chronic tolerance doses, man sometimes developed leukopenia due to lymphocytopenia, and macrocytic anemia. These changes always disappeared, but in varying intervals of time. All radioisotopes studied produced lymphocytopenia as the first indicator of effect, even in the absence of histologic evidence of changes in the lymphatic tissue of the body (animals). However, as demonstrated in the case of mouse ovarian tumors, pathologic changes might occur in the absence of blood and hematopoietic tissue changes at autopsy.

In studies on laboratory personnel, rarely could peripheral blood changes, notably leukopenia, be attributed to radiation. Both exposed and nonexposed groups often developed similar blood changes from extraneous causes (e.g., rubella). In other words, no blood changes could be found which occurred in the tolerance range of radiation exposure, and it was finally concluded that the appearance of hematologic changes should be considered very serious and indicative, probably, of overexposure beyond tolerance doses.

THE TREATMENT OF POLYCYTHEMIA VERA BY SPRAY IRRADIATION. *W. Richardson and L. L. Robbins*. New England J. Med. 238: 78-82, 1948.

This report summarizes sixteen years of experience with x-ray therapy in polycythemia vera. Spray irradiation is given with a target distance of 215 to 250 cm, over a field from neck to knees, a kilovoltage of 200, 0.5 mm copper and 1.0 mm aluminum filtration. Daily dosage varies from 20 to 30 r measured in air and the total dose is approximately 300 to 500 r in any one series of treatments divided between anterior and posterior fields. Treatment is stopped if white blood count falls below 5-6000.

Twenty-eight cases of polycythemia vera treated in this manner are reported with a five and one half year average follow-up. Radiation sickness is minimized in this report. Results obtained compare very favorably with the best results achieved by radioactive phosphorus with remissions of as long as eight years following one course of treatment. One patient developed aplastic anemia. No patients developed leukemia or a leukemoid picture. This latter is of particular interest in view of recent case reports of acute leukemia following radioactive phosphorus treatment.

PRIMARY AND SECONDARY VACUOLES IN THYMIC CELLS EXPOSED IN VITRO TO X-RAYS. *R. Schrek*. From Tumor Research Unit, Veterans Administration Hospital, Hines, Illinois. J. Cell and Comp. Physiol. 31: 203-224, 1947.

When suspensions of finely minced rat or rabbit thymus are incubated at 37°C, they undergo certain aging and degenerative processes which are manifested as vacuolar-like structures by dark-field illumination. In similar suspensions irradiated with 1000 r, the development of these structures is accelerated. Irradiation also decreases the number of viable cells as indicated by their resistance to a 1:2000 solution of eosin in Tyrode. Two types of vacuoles were observed in dark-field preparations. The primary ones were either single or multiple, small or large, usually round and clearly outlined. Secondary vacuoles were

large, dark, and round or oval Feulgen preparations revealed that the primary vacuoles were intranuclear and that the secondary vacuoles actually represented pyknotic nuclei. When the latter were extruded they behaved as spherical fluid globules immiscible with water. A hypothesis of the action of x-rays on lymphocytes is discussed.

HEMORRHAGIC DISEASES AND BLOOD COAGULATION

HEPARINEMIA (?) AN ANTICOAGULANT IN THE BLOOD OF DOGS WITH HEMORRHAGIC TENDENCY AFTER TOTAL BODY EXPOSURE TO ROENTGEN RAYS *J G Allen, M Sanderson, M Mslham, A Kirschon, and L O Jacobson* From the Department of Surgery, University of Chicago, and the Argonne National Laboratory, Chicago, Ill. *J Exper Med* 87: 71-80, 1948

Dogs exposed to 450 units of roentgen irradiation over the whole body developed infection and hemorrhage associated with neutropenia, thrombocytopenia and prolonged clotting and bleeding times. The prothrombin time remained normal until about twenty-four hours before death, and the concentrations of calcium, phosphorus and magnesium in the blood were not altered. Actual measurements of fibrinogen were not made, but the formation of clots was interpreted as evidence of the presence of fibrinogen. Delay or absence of clot retraction was related to platelet deficiency. The blood of irradiated animals appeared to gel before an actual clot was formed, and the gelled blood could be reverted to a fluid state if shaken before a solid clot formed.

Toluidine blue and protamine sulfate, substances known to inhibit the action of heparin, restored clotting time to normal and were the only agents effective in arresting hemorrhage in the dogs. Transfusions, vitamin K and vitamin C did not alter the hemorrhagic state. It is concluded that the bleeding tendency of the irradiated dogs was due, at least in large part, to the presence in the circulation of an anticoagulant whose properties were indistinguishable from those of heparin. The material isolated with difficulty from the blood of the dogs appeared in no way dissimilar from a standard sodium heparin salt, but was classed as heparin-like because the exact identity of heparin itself is unknown.

The contention that bleeding was not due to thrombocytopenia alone was supported by the observations (1) that the reduction of platelets did not always coincide with the onset of bleeding, and (2) that toluidine blue and protamine sulfate stopped the tendency to bleed but did not elevate the platelet count.

In connection with this report, the highly beneficial effect of rutin in irradiated dogs described by Rekers and Field (*Science* 107: 16-17, 1948) is of considerable interest. It appears that loss of vascular integrity may be another factor to be considered in exploring the mechanisms responsible for hemorrhage in irradiated animals.

L E Y

HYPERHEPARINEMIA THE CAUSE OF THE HEMORRHAGIC DISEASE PRODUCED BY TOTAL BODY EXPOSURE TO IONIZING IRRADIATION *J G Allen* From the Department of Surgery, University of Chicago. *Fed Proc* 6: 68, 1947

During the course of investigations on the effects of atomic radiations on living tissues, it was found that such ionizing radiations often resulted in multiple petechiae and death of a hemorrhagic diathesis. The reduction in platelets was not the entire answer to the development of the hemorrhagic tendency, for these patients showed, in addition to a reduction in platelets and an increase in bleeding time, a marked prolongation of the coagulation time. Further studies disclosed that the blood often contained an anticoagulant, the nature of which seemed to be heparin, for anti-heparin materials (toluidine blue, protamine) restored the coagulation time to normal both *in vivo* and *in vitro*. The return of the coagulation time to normal occurred independently of the platelet level, which usually remained low. Calcium, phosphorus, magnesium, prothrombin time, and fibrin formation were all normal in these cases. Finally, when dogs were exposed to ionizing radiation over the body, their plasma was found to contain an anticoagulant having the activity of heparin.

The mode of production of excessive plasma heparin by body irradiation remains to be determined. In the light of such studies, the reported effect of x-radiation in reducing the coagulation time of the blood of patients with hemophilia (Ostro and Macht, *South M J* 39: 860-867, 1946) must be held in abeyance until confirmatory evidence is presented. Certainly it would be strange if the hemophilic

patient, who already, according to one school of thought, harbors an excess of heparin in his plasma should behave in an opposite manner to the normal individual in the response to irradiation

S.E.

CLOTTING DEFECT IN HEMOPHILIA DEFICIENCY IN A PLASMA FACTOR REQUIRED FOR THROMBOPLASTIN LIBERATION FROM PLATELETS *K M Brinkhaus* From the Departments of Pathology, State University of Iowa and University of North Carolina *Fed Proc 6 389-90, 1947*

The author suggests that a plasma factor is involved in the release of thromboplastin from platelet and that the factor is deficient in patients with hemophilia. Normal citrated plasmas which coagulate slowly on recalcification were prepared by prolonged centrifugation at 2°C in glassware treated with silicone. Such plasmas were much less effective than ordinary plasmas in correcting the delayed clotting of platelet-free hemophilic plasma, but retained their corrective effect on the coagulation of whole hemophilic blood. After the addition of washed suspensions of platelets, normal or hemophilic, the plasma regularly corrected the coagulation defect of hemophilic plasmas. The platelet suspensions themselves did not do so. It must be concluded, therefore, that the presence in one medium of both platelets and plasma was required for the production of whatever substance was involved in the reduction of hemophilic coagulation time. Brinkhaus prefers to consider that some plasma factor acts upon platelets to release contained thromboplastin. Quick (*Fed Proc 6 284, 1947*) believes that the platelets release something which activates a thromboplastin-precursor in the plasma. The normalcy of hemophilic platelets is indicated by both their investigations, and the occurrence of some defect in the plasma of hemophilia is now generally accepted. Whether the defect consists of absence of thromboplastin, absence of activator, absence of some unspecified globulin, or excess of heparin still remains to be unequivocally demonstrated.

S.E.

LES HEMATOMES INTRACRANIENS DES HÉMOPHILES (INTRACRANIAL HAEMORRHAGE IN HAEMOPHILIACS)

Paillard, J Boudouresque, J Tamalet *Sem Hop Paris 24 432-436, 1948*

Only a few isolated cases of intracranial hemorrhage in hemophiliacs have been reported. The following 3 cases of this quite exceptional complication of hemophilia are thus of some interest.

The 3 cases are almost identical. After a minimum amount of trauma (a slight fall on to the head in two cases, and compression of the neck and jugular veins in the third), the downhill course was progressive after an initial symptomless period. In 2 of the cases, there were signs of progressive intracranial hypertension, with increasing headache, somnolence and papillary congestion, together with motor signs and aphasia. The diagnosis was clear. The great problem was treatment.

In all 3 cases, surgical intervention was necessary. Great subdural hematomata composed of liquid blood with numerous clots were found. All 3 patients died despite a transfusion one hour before operation. Intervention was inevitable in all 3 cases because of the onset of coma. The patients died, 1, 2, and 24 hours, respectively, after the operation. In none of the cases were thrombin, fibrin, gelatine or oxycellulose used.

It is to be regretted that the authors do not give more details of the quantity and number of transfusions, nor of the clotting time, information which would be of great value in ascertaining the exact cause of the operative failures.

J.P.S.

QUANTITATIVE STUDIES ON THE COAGULATION DEFECT IN HEMOPHILIA *A J Quick* From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee *Fed Proc 6 284, 1947*

The three commonly held theories of the pathogenesis of hemophilia include absence of some factor from hemophilic plasma, presence of some anticoagulant in hemophilic plasma, and poor breakdown of hemophilic platelets to initiate coagulation. Recent studies by Quick tend to reconcile, according to him, the differences between the first and the third of these theories.

Quick found that the serum obtained immediately after hemophilic blood has been allowed to coagulate contains unchanged fibrinogen and virtually as much prothrombin as the original blood. Incubation at 37°C produces coagulation of all the fibrinogen in one hour, but the prothrombin is unchanged (1 c.

only a small amount of thrombin is formed) Thromboplastin converts the prothrombin of hemophilic blood to thrombin stoichiometrically, not enzymatically Platelets, however, contain little thromboplastin, for when an extract of platelets is added to prothrombin in plasma, little conversion to thrombin occurs Normal plasma deprived of platelets by centrifugation shows a poor conversion of prothrombin to thrombin, but when such platelet-free plasma is added to hemophilic blood, the prothrombin of this blood is rapidly changed to thrombin and rapid clotting follows When normal platelet-free plasma is added to hemophilic plasma also low in platelets, little thrombin is formed

These data signify that thromboplastin may occur in plasma in an inactive form, and Quick believes that the platelets furnish an agent which enzymatically converts this inactive thromboplastin to an active form Hemophilic platelets behave normally, but hemophilic plasma, according to this work, lacks the inactive thromboplastin, and hence coagulates poorly Quick feels that the inactive thromboplastin is probably identical with Howell's plasma thromboplastin and with the anti-hemophilic globulin of the Harvard investigators The nature of the latter substance has not yet been chemically determined, but its identity with thromboplastin is an interesting, if undemonstrated, suggestion

S E

THROMBOPLASTIN IN THE URINE OF NORMAL AND HEMOPHILIC MEN *L M Tocantins and J N Lindquist*

From Jefferson Medical College, Philadelphia *Fed Proc* 6 215, 1947

Fresh human urine was found to contain thromboplastic substances which act by accelerating the conversion of prothrombin to thrombin Urine from hemophilic patients was found to have as high or even higher activity in this regard as urine from normal men The source of this material, and its nature, are not clear, but the authors suggest that it may come from the kidney itself, or may be the product of disintegrated tissue or blood cells cleared from the blood by the kidneys

S E

THE PROTECTIVE ACTION OF RUTIN AGAINST CAPILLARY INJURY *A M Ambrose and F DeEds* From the Pharmacology Division, Bureau of Agricultural and Industrial Chemistry, U S Department of Agriculture, Albany, California *Fed Proc* 6 306, 1947

These workers studied capillary permeability in rabbits by means of intravenous trypan blue injections the dye accumulates in areas of injury Capillary injury was produced in the rabbit's abdominal wall by various agents including chloroform, histamine, and negative pressure Untreated rabbits were compared with animals who had previously received rutin

In 22 rabbits to whom rutin had previously been administered, the appearance of trypan blue dye in chloroform-produced wheals was delayed as much as eight times above control, nonrutinized animals (Dosages and times are not given in this brief report) Rutin also prevented the appearance of dye after the application of negative pressure to the abdominal skin These are further data to be added to the rather meager experimental evidence supporting the clinical impression that rutin has a beneficial effect on capillary resistance

S E

BLOOD LEVELS OF CERTAIN CONSTITUENTS IN NORMAL ADULTS BEFORE AND AFTER INGESTION OF RUTIN *E*

Papageorge and F Adair From Emory University, Georgia *Fed Proc* 6 283, 1947

Despite the vague clinical impression that rutin is useful in certain patients with excessive capillary permeability, little objective experimental evidence has been presented to confirm this feeling The authors placed 15 normal adults on a low ascorbic acid diet for four weeks, and then tested them during successive two week intervals with rutin in the absence of ascorbic acid, ascorbic acid without rutin, and both drugs together The dose of rutin was 100 mg daily, as was also that of ascorbic acid

Rutin was found to have no influence on the serum levels of cholesterol, calcium, sodium, or vitamin K Ascorbic acid levels, although done, were not reported, but they were said to suggest that rutin tends to maintain a high serum level of this substance The relationship of these findings in the normal individual, to that in the abnormal patient with forms of vascular purpura (in whom rutin may be of value), remains to be found There is still no agreement on the mode of action of rutin, and little beyond an impression as to whether it is even efficacious

S E

SOME FACTORS INFLUENCING THE STRUCTURE AND RATE OF FORMATION OF FIBRIN CLOTS *J D Ferry, J T Fdsall, P R Morrison, V Kmet, and W F Leiter* From the Department of Physical Chemistry, Harvard Medical School, Boston Fed Proc 6 250-251, 1947

The authors studied fibrin formation in solutions of human fibrinogen and thrombin, in the absence of prothrombin and of fibrinolytic materials. They found that the initial rate of coagulation was linearly proportional to the concentrations of thrombin (within certain limits) and fibrinogen. By altering the pH, ionic strength, and chemical composition of the medium, they were able to produce various types of clot structures, including a clot which was coarse and readily contractile, and a clot which was translucent and friable.

S.E.

THE FINE STRUCTURE OF CLOTS FORMED FROM PURIFIED BOVINE FIBRINOGEN AND THROMBIN. A STUDY WITH THE ELECTRON MICROSCOPE *C V Z Hahn and K R Porter* From the Department of Pathology, Harvard Medical School, Boston, Mass., and the Laboratories of the Rockefeller Institute for Medical Research, New York, N. Y. J. Exper. Med. 86 285-292, 1947

A technic is described for preparing clots from bovine fibrinogen and thrombin which are suitable for study with the electron microscope. The observations of this report are concerned chiefly with the effects of alterations of pH. It was found that clots are composed of meshworks of single and compound fibers, and that unit fibers have greater diameter and greater tendency for lateral association into compound fibers as the pH is decreased from 8.5 to 6.3. Cross striation of unit fibers was a striking feature of all clots studied. The periodicity of these striations was found to be constant (approximately 250 Å) and there was a precise coincidence of striations of unit fibers when these were associated side by side to form compound fibers.

The authors present a cautious discussion of the possible relationship between their observations and the supposed molecular structure of fibrinogen. Excellent photographs are included in the paper.

L.E.Y.

HEMOSTATIC PROPERTIES OF HEMOLYTIC AGENTS *M E Muhrer and A G Hogan* From the Department of Agricultural Chemistry, University of Missouri Fed Proc 6 280, 1947

This paper attempts to elucidate the increased coagulability of blood following certain hemolytic episodes. The authors, having found a sharp drop in coagulation time in hemophilic swine immediately after the injection of hemolyzed erythrocytes, determined that the same effect could be obtained by giving acetylphenylhydrazine, thioldiphenylamine, and other hemolytic agents. Analysis revealed that, simultaneous with the reduction in coagulation time, there was a sharp decrease in the fibrinogen, the cell volume, and the amount of prothrombin [sic]. For certain agents—notably saponin and sodium oleate—the fall in coagulation time was followed by a negative phase during which the coagulation time was increased above normal despite an increase in fibrinogen. This refractory phase was due to a further decrease in the amount of prothrombin which occurred with these agents.

It is not clear to what the reduction in coagulation time could be attributed. It should be pointed out that, clinically, transfusion reactions, which result in severe intravenous hemolysis, result in a hemorrhagic tendency, rather than the opposite, but presumably this is the result of damage to the endothelial lining of the vascular system.

S.E.

THROMBOPLASTIC FACTORS IN THE ESTIMATION OF PROTHROMBIN CONCENTRATION *C L Conley, W I Morris, II* From the Department of Medicine, Johns Hopkins University and Hospital, Baltimore, Maryland Am J M Sc 215 158-169, 1948

The purpose of this study was to determine, by Quick's method, whether prothrombin determinations in which different thromboplastin solutions were used gave comparable results. Rabbit foam emulsion prepared by the authors, two acceptable commercial thromboplastin preparations, and viper venom were employed. Very divergent results were obtained on human hypoprothrombic plasmas when saline dilution curves were used for reference. In dogs, the authors found that barium sulfate-treated plasma behaved more like that of dicumarolized (prothrombin-free) plasma than did plasma treated with aluminum.

hydroxide Even with human plasma prepared with barium, discrepancies between various thromboplastins persisted The authors point out the apparent complexity of the factors involved This again emphasizes the difficulty in quantitating the prothrombin test and in comparing results of various laboratories using different thromboplastin preparations

C A F

DICUMAROL POISONING *A J Draper, Jr* From Charlotte Memorial Hospital, North Carolina *J A M A* 136 171-172, 1948

This case report of a patient whose self medication with 8 or 10 'tablets of dicumarol was followed by hematuria, bloody diarrhea, oral bleeding, and multiple ecchymoses, outlines a method of treatment for such cases of excessive dicumarolization The patient received 150 mg of vitamin K as synkayvite on the first day (120 intravenously in two doses, 30 mg intramuscularly), and 60 mg of synkayvite'' daily by vein on the second, fourth, and fifth day Response was prompt and sustained

S E

IDIOPATHIC THROMBOCYTOPENIC PURPURA A STUDY OF THREE CASES WITH SPECIAL REFERENCE TO CHANGES IN THE MEGAKARYOCYTES *E H Valentine* From Temple University Medical School and Hospital, Philadelphia, Pennsylvania *Am J M Sc* 214 260-267, 1947

Bone marrow studies of three cases of idiopathic thrombocytopenic purpura showed an increase in total number and a striking decrease in platelet forming in megakaryocytes These studies give further confirmation to the previous report of Limarzi and the careful morphologic studies of Dameshek and Miller, and emphasize the importance of sternal puncture in the diagnosis of this form of purpura

C A F

TWO CASES OF THROMBOCYTOPENIC PURPURA TREATED WITH FOLIC ACID *T H Gridley and T R Waugh* From the Department of Medicine of the Homeopathic Hospital of Montreal, (Quebec), and the Department of Pathology, McGill University *Canad M A J* 57 487-488, 1947

The first patient described was a 52 year old female who had had attacks of purpura for ten years She was found to have a platelet count of 3000 per cu mm, a prolonged bleeding time and positive Rumpel-Leede test Splenectomy was followed by a remission lasting only a few months Thrombocytopenic purpura again developed and persisted with varying severity for eighteen months The platelet count rose and bleeding ceased at this time following administration of 10 mg of folic acid per day This form of therapy was continued for an additional fourteen months without exacerbation of symptoms The results in this case of idiopathic thrombopenic purpura are considered sufficiently encouraging to justify further clinical trials

In the second case presented, thrombopenic purpura followed administration of bismuth Since use of this drug was apparently discontinued before folic acid was given, the favorable response described cannot be attributed to folic acid therapy

L E Y

STUDIES ON THE INTRAVASCULAR THROMBOPLASTIC EFFECT OF TISSUE SUSPENSIONS IN MICE I THE REACTION OF MICE TO INTRAVENOUS INJECTIONS OF A SEDIMENTABLE TISSUE COMPONENT II A FACTOR IN NORMAL RABBIT SERUM WHICH INHIBITS THE THROMBOPLASTIC EFFECT OF THE SEDIMENTABLE TISSUE COMPONENT *L Thomas* From the Department of Pediatrics, Johns Hopkins University Medical School and the Harriet Lane Home for Invalid Children, Baltimore, Maryland *Bull Johns Hopkins Hosp* 81 1-42, 1947

Intravenous injections of suspension of mouse brain tissue into mice were observed to produce generalized ataxia, clonic convulsions and coma This reaction was associated with cessation of capillary flow and formation of cell aggregates along with shortening of the coagulation time The coagulation time then became prolonged and the mice were resistant to toxic doses of the suspension The factor in tissue suspensions which produced the reaction could be sedimented at 12 000 r p m, a procedure which increased its heat stability The active factor was considered to be thromboplastin and its coagulating effect could be inhibited by heparin and congo red Incubation with normal rabbit serum was found to

inhibit the activity of the suspensions. The factor in normal serum producing the inhibition was found within the globulin fraction and was thermolabile at 60°C. A second factor, probably calcium alone, was shown to be necessary for the inhibitory activity of serum. These observations are of unusual interest in that they remove the study of blood coagulation from the highly artificial environment of the glass container to *in vivo* observations. Demonstration of the reversability of coagulation reaction *in vivo*, at least in its early phases, introduces a new concept.

ETUDE DE 114 CAS DE SYNDROMES HÉMORRAGIQUES EXAMINÉS EN L'ESPACE D'UN AN (ETUDE CRITIQUE DES ÉPREUVES FONCTIONNELLES DE L'HEMOSTASE) (STUDY OF 114 CASES WITH HEMORRHAGIC SYNDROMES EXAMINED OVER ONE YEAR [CRITICAL STUDY OF FUNCTIONAL TESTS OF HEMOSTASIS]) A. Tzanck, J. P. Soulier and S. Efros. From the National Blood-Transfusion Centre, Paris. *Rev. Hémat.* 2, 478, 1947.

The interest of this detailed study lies in the fact that all the 114 cases have been studied with the aid of the same technique over one year. The first part of the article is a critical study of these techniques. The hemorrhagic syndromes are then classified according to the results of tests for hemostasis and the stage of hemostasis involved.

The classification was therefore as follows:

1. Involvement of the third, or plasma stage of hemostasis. These are the true disorders of coagulation (e.g. hemophilia, hypofibrinemia, hypothyrombinemia, anti-coagulants).
2. Disorders of the second, or thrombocyte stage of hemostasis (e.g. thrombocytopenic purpuras and the very rare thrombasthenias).
3. The purpuras without thrombocytopenia but with abnormal results for one test (e.g. bleeding-time or capillary resistance).
4. Hemorrhagic syndromes in which all the tests for hemostasis are normal (e.g. allergic purpuras, dermatologic purpuras, and hemorrhagic syndromes without purpura).
5. Unclassifiable syndromes of the Banti type in which many hemostatic factors are involved.

The article ends with some therapeutic applications, in particular the necessity of studying the megakaryocytes in the marrow before every splenectomy, and the importance of neuro-endocrine factors in the involvement of the first or 'parietal' stage of hemostasis.

FUNDAMENTAL WORKING CONCEPTS IN THE STUDY AND MANAGEMENT OF PATIENTS WITH ABNORMAL BLEEDING. L. M. Tocantins. From the Department of Medicine, Jefferson Medical College and Hospital, Philadelphia, Pa. *Amer. Practitioner* 2, 479-485, 1948.

This paper elaborates on the thesis that abnormal bleeding results from an upset in the balance between hemostatic functions and forces exerting stresses on the vessels. The various extrinsic (physical and chemical trauma) and intrinsic (muscular contractions, blood pressure, etc.) forces which are often disregarded by the practitioner, are enumerated and their importance with respect to diagnosis and treatment is emphasized. The use of splints and elastic bandages in the management of bleeding in hemophiliacs is illustrated, and the necessity for minimizing surgical trauma in these patients is stressed.

L E Y

THE HEMORRHAGIC TENDENCY IN CONGESTIVE SPLENOMEGALY (BANTI'S SYNDROME). L. M. Tocantins. From the Division of Hematology, Department of Medicine, Jefferson Medical College and Hospital, Philadelphia, Pennsylvania. *J. A. M. A.* 136, 616-621, 1948.

This is a discussion of the etiologic factors of the hemorrhage in Banti's syndrome, based upon a study of 22 patients in whom the diagnosis was made. All 22 patients had various forms of hemorrhage, of which hematemeses and melena were most common (17 patients). It is pointed out that the spleen may shrink with acute hemorrhage, so that it is not palpable on admission of the patient to the hospital, but becomes palpable only several days (as long as ten days) later. The periodicity of episodes of hemorrhage is considered to be due to a cycle of (1) gradual increase in portal hypertension, which gives rise to (2) rupture of vessels (esophageal, gastric, hemorrhoidal), which results in (3) hemorrhage, giving (4) decompression, which ultimately gives rise to (5) another increase in portal tension, etc. The actual

causes of bleeding are (1) varices of the esophageal and rectal veins, with weakening of the vein walls, (2) thinning of the mucosa overlying these veins, (3) thrombocytopenia, (4) hypoprothrombinemia due to hepatic damage. Treatment in such cases includes the use of transfusions, vitamin K, bed rest, and pressure at the site of bleeding, if necessary. Splenectomy was performed in 9 of the 22 patients, with improvement and long survivals in most.

S E

THROMBOPLASTIC PROPERTIES OF PENICILLIN AND STREPTOMYCIN *D I Macht* From the Department of Pharmacology, Sinai Hospital, Baltimore, Maryland *Fed Proc* 6 160, 1947

Investigations of the effect of penicillin on the coagulation time are somewhat confused at the present time. Moldovsky and his co-workers (*Science* 102 38, 1945) first pointed out that the parenteral or oral administration of penicillin to normal subjects was followed by a marked fall in the coagulation time of the blood. The degree of reduction was inversely correlated with the level of penicillin in the blood, but the effect persisted after penicillin was no longer demonstrable in the blood. Hines and Kessler, on the other hand (*J A M A* 128 744, 1945) found that penicillin sometimes aggravated the effect of heparin (i.e., tended to increase the coagulation time) in certain patients.

Macht, in this report, found a reduction in the coagulation time of patients receiving parenteral penicillin (or streptomycin), but was unable to find such an effect in patients with hemophilia. Some 200 studies were therefore carried out on rabbits and cats, which showed a shortening of the coagulation time after the injection of penicillin. Penicillin acted within thirty minutes to cause a reduction of the coagulation time, and continued to act for several hours. Penicillin X was found the most potent in this regard, penicillin F, weakest, and penicillins K and G, intermediate. (See also Macht, *Science* 105 313-314, 1947.)

Clinical significance of these findings must await evaluation of these and contradictory results, especially those of Fleming and Fish (*Brit M J* 2 242, 1947). These authors found that a concentration of penicillin as little as 340 units per cc increased the coagulation time of blood, and 12,000 units per cc might result in incoagulability. They were led to their investigations by the finding that apicectomy, a dental procedure which requires good local coagulation of blood for its efficacy, was being hampered by lack of coagulation in patients who had had penicillin powder instilled into the wound. They suggest, therefore, that penicillin not be used locally if coagulation is important, but comment that the parenteral use of penicillin, which results in small unitage of the drug in the blood, has no effect on the coagulation time.

S E

PURPURA AND INTUSSUSCEPTION *H Wolfsohn* From the Fulham Hospital, London, England *Arch Dis Childhood* 22 242-247, 1947

The author reports the combination of Henoch-Schönlein purpura and intestinal intussusception in a 5 year old child. Four days before admission to the hospital, the patient suddenly developed migrating polyarthritides, involving successively the knee, the elbow and the wrist, and then complained of severe abdominal pain and purpuric spots on the buttocks and arms. On physical examination, in addition, a mass was felt in the right iliac fossa. Blood studies showed no thrombocytopenia, and bleeding time, coagulation time, and tourniquet tests were negative. At exploratory operation, an ileo-ileal intussusception was found and repaired. The boy subsequently recovered completely, except for a single attack of abdominal pain plus bloody stool six months after operation.

There are nineteen previous reports in the literature of intestinal intussusception in association with Henoch-Schönlein purpura. Sixteen of the total of 20 cases occurred in males, but both Henoch-Schönlein purpura itself, and intestinal intussusception without purpura, are more common in males than in females. Joint pains were present in 11 of 17 reported cases, and purpura was present in all 20.

The coincidence of the two conditions—intussusception and purpura—is too great to be accounted for by chance. The author considers explanations for this coincidence, and notes that it is probable that extravasation of blood occurs into the various coats of the small intestine, the resulting mass of submucosal blood favoring intussusception. Recovery from this complication occurred in 12 of the 20 cases in the literature, either spontaneously or following operative interference. The causes for the purpura

which is supposed to be allergenic, remain obscure, in this case, there was no evidence in family or patient for allergy

S.E

LEUKOCYTES AND LEUKOCYTIC DISEASE

EXPERIMENTAL ATTEMPTS TO TRANSMIT INFECTIOUS MONONUCLEOSIS TO MAN *A S Evans* From the Section of Preventative Medicine, Yale University School of Medicine, New Haven, Conn Yale J Biol & Med 20 19-26, 1947

Twenty-one experiments with human volunteers were carried out in an attempt to transmit infectious mononucleosis by means of serum, whole blood and throat washings. Transitory symptoms consisting of pharyngitis, lymphadenopathy and lymphocytosis with atypical cells appeared in a few subjects, but in no instance did an unequivocal example of the disease develop. Failure to transmit the disease may be due to extreme lability of the agent or low degree of susceptibility of the 17 subjects. These results indicate that the refusal of some blood banks to accept individuals who have a past history of mononucleosis is overcautious.

R S E

INFECTIOUS MONONUCLEOSIS A REVIEW *B R Gendel and J E Cottrell* From the Medical Service, Veterans Administration Medical Teaching Group, Kennedy Hospital, Memphis 15, Tenn Am Practitioner 2 472-478, 1948

Nearly all of the important aspects of infectious mononucleosis are discussed briefly in this up-to-date review with well-chosen bibliography. Of particular interest are the references to jaundice, thrombocytopenia, recently reported autopsy and biopsy findings and experimental transmission of the disease.

L E Y

GRAVES ACCIDENTS DE SUFFOCATION DANS DEUX CAS DE MONONUCLEOSE INFECTIEUSE (SERIOUS COMPLICATION OF ASPHYXIA IN TWO CASES OF INFECTIOUS MONONUCLEOSIS) *A Lemierre, M Morn and M Almon* Bull et mém Soc méd d hôp de Paris, 51-54, Jan 16, 1948

The first case is that of a pseudo-phlegmonous throat infection. The finding of Klebs-Loeffler bacilli in the throat, led to the injection of 100,000 units of serum. The general condition was good, the temperature was 39.7°C. The blood count showed 5,620 00 red cells, and 21,000 white cells of which only 50 per cent were polynuclears. On the eighth day of the disease, the movements of respiration began to be obstructed both behind and below the sternum. Respiration which had been noisy for several days now became more difficult. The dyspnea increased the following day and the patient died suddenly on the ninth day of the disease. Pericardial puncture provided 20 cc of liquid which gave a positive Paul Bunnell reaction. No autopsy was performed.

The second case characterized by the severity of the pharyngeal signs, also caused one to think of diphtheria (the culture was negative). A diagnosis of infective mononucleosis was made from the blood count (16,000 leucocytes, of which 42 per cent were polymorphs) and the positive Paul Bunnell reaction. Laryngoscopic examination showed massive hypertrophy of the lingual tonsil which resembled that of the pharyngeal tonsil, and appeared to be responsible for the severe dyspnea.

On the seventh day, the dyspnea increased with obstruction both above and below the sternum. Tracheotomy was performed. The signs disappeared and the tube was removed on the twelfth day. Cure resulted.

The authors attribute the progressive dyspnea to the severity of the pharyngeal signs. It is possible that a neurologic factor plays a part and the torpor of the two patients was intense.

We think that it is interesting to note these observations which, added to the reported cases of rupture of the spleen, show that prognosis should be reserved despite the usual benignity of infective mononucleosis.

J P S

ACUTE INFECTIOUS LYMPHOCYTOSIS *S. Israel's* Winnipeg, Manitoba, Canada *Am J Dis Child* 74 722-724, 1947

The author gives a brief review of the literature on acute infectious lymphocytosis and reports the case of a 4 year old girl who appeared to be suffering from this disease. She had vomited, was drowsy, had enlarged tonsils and an injected pharynx, but spleen and lymph nodes were not palpable. The highest white blood cell count was 39,350 at which time there were 69 per cent small lymphocytes. Four days later when the lymphocyte count was the same, there were 8 per cent eosinophils, a finding also noted by others. Tibial marrow showed 22 per cent lymphocytes. Sheep cell agglutination test was negative. The spinal fluid was not examined.

There is an apparent need for studies on the etiologic agent of this disorder.

LEY

LA NEUTROPENIE FAMILIALE (FAMILIAL NEUTROPENIA) *J. Bousser and R. Neydt* Sang 18 521-529, 1947

The authors present a study of a very rare affection, observed by Gansslen in 1941 in 4 families.

They describe here 3 members of the same family with a permanent leukopenia of between 2,500 and 3,500, with a neutropenia of between 35 and 50 polymorphs, without modification of the Arneht count. The red cell and platelet counts (in the case in which these last were estimated) were normal. Nothing abnormal was found clinically, the general state of health was good and the condition was discovered by chance. These subjects did not seem to be particularly prone to infection.

In the case most completely studied by the authors, the myelogram showed 49 per cent of granular cells and 41 per cent of erythroblasts. This defect is transmitted as a dominant non-sex-linked character.

The authors discuss the differential diagnosis between this condition, the splenic neutropenia of Wisemann and Doan, the chronic sporadic neutropenias and Fanconi's disease.

One should add that there may be a connection also between this condition and the syndrome recently described by Estren and Dameshek (*Am J Dis Child* 73 671, 1947).

JPS

CONVERSION OF ACUTE INTO CHRONIC LEUKEMIA *R. Isaacs* From the Hematology Laboratory, Michael Reese Hospital, Chicago *Fed Proc* 6 394, 1947

Six patients with acute leukemia (blasts in the peripheral blood) showed a change in the blood picture to that of chronic leukemia, plus an associated remission in the clinical picture, after the oral ingestion of crude tyrosinase. Details are not given, and no follow-up is reported, beyond the statement that the patients lived from five months to one year after the initial diagnosis of acute leukemia.

SE

CHANGES IN BLOOD LYMPHOCYTES IN NORMAL AND RESISTANT RATS FOLLOWING TRAUMATIC SHOCK *D. D. Munro and R. L. Noble* From the Research Institute of Endocrinology, McGill University *Fed Proc* 6 168-169, 1947

The production of traumatic shock in normal rats was found to be accompanied by a marked relative and absolute lymphocytopenia in the circulating blood. The greater the trauma, it was found, the greater the reduction in lymphocytes. In all cases which survived, however, the lymphocytes had returned to normal within forty-eight hours. When shock was so severe that death ensued, the most severe depression of lymphocytes occurred.

When, however, identical trauma was applied to trauma-resistant rats, it was found that the initial lymphocyte level was higher than in trauma-sensitive rats, the fall in lymphocytes less, and the recovery quicker. The authors believed, therefore, that the degree of resistance could be related to the lymphocyte level after trauma.

These are further studies in line with the general thesis that the lymphocytes and lymphocyte-producing areas of the body are important in the immune mechanisms of the body.

SE

STUDIES ON ADRENOCORTICAL FUNCTION IN RELATION TO LYMPHATIC LEUKEMIA *L. Levin* From the Department of Hematology, Michael Reese Hospital, Chicago Fed Proc 6 270, 1947

The author presents further evidence of a possible relationship between the adrenal cortex and lymphatic leukemia, in line with the studies of White and Dougherty of a reciprocal balance between adrenal cortex and lymphocyte-producing centers of the body. The present work attempts to discover the nature of the anatomic alterations in the adrenals of mice with lymphatic leukemia.

In Furth's AK strain of mice, lymphatic leukemia is associated with an increase in the size of the adrenal glands, but this occurs only in males (38 per cent increase) and not in females (5 per cent increase). Levin analyzed the adrenals, and found that in all mice, male and female, with lymphatic leukemia, the concentration of the cholesterol in the adrenal was lower after leukemia (2.64 per cent) than before leukemia develops (4.78 per cent). He found too that injection of pituitary adrenocorticotrophic hormone did not affect the course of the disease or the alterations in the adrenals, even though it was given from the time of transmission of leukemic cells. Attempts to study the excretion of 17-ketosteroids in clinical patients with lymphatic leukemia, in order to test their adrenal cortical activity, yielded equivocal results.

These results suggested that there might well be a relationship between the adrenal and lymphatic leukemia, although they did not prove such a relationship.

SE

THE POVERTY OF THE IMMUNOLOGICAL MECHANISM IN PATIENTS WITH HODGKIN'S DISEASE *I. N. Dubin*
The Division of Pathology and Bacteriology, University of Tennessee College of Medicine, Memphis, Tennessee Ann Int Med 27 898-913, 1947

Records of 262 patients with Hodgkin's disease were reviewed for evidence of their ability to form antibodies. Only 1 of 38 patients showed a positive tuberculin in contrast to an expected frequency of 50 per cent. There was likewise a low incidence of positive serologic tests for syphilis and apparent inability to make antibodies against Brucella and typhoid vaccine.

The authors feel that this immunologic deficiency is attributable to the damage to the reticuloendothelial system by the disease, and that this explains the susceptibility of these patients to bacterial infection.

C A F

RELATION OF THE ADRENALS TO IMMUNITY *A. White* From the Department of Physiological Chemistry, Yale University, New Haven, Conn Bull New York Acad Med 24 26-31, 1948

The author presents a brief review of the newer concepts of hormonal factors concerned in immunity, a field in which he and his associates have made important contributions. Particular reference is made to the effects of adrenal cortical steroids in stimulating the development of phagocytic cells in lymphoid structures and in accelerating the release of gamma globulin from lymphocytes. It is further pointed out that these steroids may produce an elevation of antibody titre either in a hyperimmunized animal or in a previously immunized animal with no circulating antibody. Such observations suggest to the author that pituitary-adrenal cortical control of lymphocyte structure and function may play an important role in anamnestic responses and may explain why various unrelated stimuli produce these responses. It is acknowledged, however, that antibody production does not cease in adrenalectomized animals and that other recent experiments make it clear that much remains to be learned concerning the relation of adrenals and other endocrine glands to immunity.

L E Y

USE OF FOLIC ACID DERIVATIVES IN THE TREATMENT OF HUMAN LEUKEMIA *L. M. Meyer* From the Kings County Hospital, Brooklyn, New York Tr New York Acad Sc 10 99-102, 1948

This is one of a series of articles (in the same publication) comprising a symposium on the use of several derivatives of folic acid in neoplastic diseases. Other articles discuss the chemistry and synthesis of anti-folic acid compounds, and their employment in carcinoma, sarcoma, lymphoma, and Rous

chicken sarcoma The present report discusses experience with such compounds in chronic and acute leukemia, and multiple myeloma

Several different compounds were used Teropterin or pteroyl-diglutamyl-glutamic acid was used without effect on blood, bone marrow, liver, spleen, or lymph nodes, in 2 cases of multiple myeloma, 2 cases of chronic myelogenous leukemia, and 7 cases of chronic lymphatic leukemia In an additional patient with acute (lymphoblastic) leukemia, however, there was a fall in the number of white cells and blasts in the peripheral blood, a reduction in the percentage of blasts in the marrow with a corresponding increase in mature lymphocytes, and some transitory clinical improvement There was rapid relapse, however, and death

Diapterin (pteroyldiglutamic acid) had a similar effect in one other patient with acute lymphoblastic leukemia

Five further cases of acute leukemia were treated with two other derivatives of folic acid, which have anti-folic-acid activity in bioassays pteroyl-aspartic acid and methyl-folic acid Similar results were noted in all these cases, namely, a reduction in the total white count in the peripheral blood, a reduction in the percentage of blasts, and a tendency for similar changes within the bone marrow All these effects were transient, although their importance is suggested by the author's comment that the possibility that their occurrence was spontaneous, rather than related to the medication, was, according to his experience, negligible

Regardless of hematologic effect, all treated patients, both in this and the other series (carcinoma, sarcoma, myeloma), felt clinically much improved It was suggested by Gellhorn, in a discussion of this paper, that this effect was not specific and might be related to the known feeling of well-being following the use of glutamic acid in mental disorders This discussor emphasized, too, that the results reported were fragmentary and not necessarily attributable to the various drugs utilized They are at least, however, suggestive, and further reports will prove of interest

TRANSFUSION JAUNDICE

HOMOLOGOUS SERUM JAUNDICE IN RECIPIENTS OF POOLED PLASMA I J Brightman and R F Korns From the New York State Department of Health, Albany, New York J A M A 135 268-272, 1948

The authors investigated the incidence of homologous serum jaundice in patients who were given plasma for therapeutic purposes, and the incidence of plasma transfusions in patients whose death was wholly or partly attributed to hepatitis No attempt was made to make a complete survey of each case, but the study was done in such a way as to give more or less minimum incidence value The site of study was New York State, exclusive of New York City, and the time, apparently, was 1946-7

Of 649 patients who received dried pooled plasma, hepatitis subsequently occurred in 29 (4.5 per cent) A statistically significant variation occurred with age 8.7 per cent of 252 patients over 50 developed hepatitis, 2.2 per cent of 319 aged 20 to 50, and none of 78 aged under 20 No jaundice occurred in 1,597 household contacts of the recipients of the plasma, including 56 contacts of jaundiced patients Calculated on the basis of an estimated 15,000 persons receiving plasma per year in the area involved, a yearly figure of some 675 cases of hepatitis might be anticipated It was impossible to determine which lots of plasma might have been responsible, although a minimum figure of 4.7 per cent of all the lots used was calculated to have been icterogenic

Of 51 deaths due to acute hepatitis, 15 patients (30 per cent) had received transfusions in the six months preceding death Of these, 12 had received only plasma, 1 had received both plasma and blood, and only 2 had received only blood American Red Cross dried pooled plasma was used in these cases as well as in the entire study

Granted incompleteness of the investigation, the results presented seem to give minimum values for icterogenicity of pooled-plasma lots The authors suggest two methods of dealing with the situation (1) ultraviolet irradiation of plasma as part of its processing, and (2) substitution of albumin which can be heated to destroy the virus before distribution, for whole plasma

S E

NEWS AND VIEWS

BLOOD CLUB

The first meeting of the newly organized BLOOD CLUB was held at Atlantic City on the evening of May 2, 1948, just prior to the meetings of the American Society for Clinical Investigation and the Association of the American Physicians. The meeting was organized by a committee consisting of William Dameshek (Boston), Carl V. Moore (St. Louis), and Maxwell M. Wintrobe (Salt Lake City). One hundred and eighteen were present at the dinner and another 25 or 30 appeared for the after-dinner discussions. Two subjects were taken up: (1) newer aspects in the pathogenesis of pernicious anemia, and (2) hemolytic mechanisms. The first subject was in the form of a round table discussion with the following panel: Maxwell M. Wintrobe, Moderator, Tom Spies, William B. Castle, Frank H. Bethell, Carl V. Moore, W. H. Sebrell, Joseph M. Ross, W. Jacobson (Cambridge, England), Robert W. Heinle, George E. Cartwright, and Thomas Jukes.

The panel was asked to discuss the following questions: Do patients with pernicious anemia respond to heptaglutamate or to the Di- and Tri-compounds? Does PGA do anything in sprue that liver extract does not? What is the present status of Wills Factor? What is the present status of experimental anemias designed to elucidate the pathogenesis of pernicious anemia and related disorders? How does one explain the role of PGA and liver extract in these conditions? What is the significance of the inhibitors? How is the action of thymine explained? What is the significance of vitamin B₁₂? What is the relation of PGA to the neurological changes in PA and to glutamic acid metabolism?

Much of the discussion centered around the physiologic activity of folic acid and its conjugates and the possible relationship of these substances to liver extract. Drs. Heinle and Bethell emphasized the rather confusing experimental results in patients with the use of folic acid conjugates. Drs. Wintrobe and Cartwright discussed the production of megaloblastic macrocytic anemia in swine with the use of folic acid inhibitors. Good results were obtained with folic acid in contrast to the negative results obtained with liver extract.

Dr. Sebrell discussed his work with folic acid in experimental anemia and leukopenia. Dr. Ross discussed the neurologic lesions developing in cases of pernicious anemia following long continued use of folic acid as the sole medication. He pointed out that the glutamic acid in the folic acid molecule might be deleterious to the central nervous system tissue. However, no definite evidence for this effect was brought forward, although some work on brain tissue slices appeared to confirm these observations. On the other hand, Dr. Jukes of the Lederle Laboratories presented data indicating that folic acid, when allowed to act on brain slices in the Warburg apparatus, showed no effect on brain tissue. Dr. Spies mentioned his work with thymine and suggested the concept that pernicious anemia was in all probability a disorder of nuclear metabolism, especially since thymine was a product of nucleic acid degradation.

Dr Castle pointed out that the introduction of folic acid and the work with the various folic acid conjugates had resulted in considerable confusion as to the etiologic picture of pernicious anemia. This was heartily agreed upon by various other speakers.

The subject of hemolytic mechanisms was discussed in a more orthodox fashion, three speakers taking up different points of view regarding the mechanisms involved in excessive blood destruction. Dr William B. Castle (Boston) discussed the mechanical aspects of hemolysis with particular reference to the mechanical fragility of the red blood cell. He pointed out that agglutinins and other abnormal substances might result in increased mechanical fragility of the red blood cells, an important physiopathologic mechanism in red cell destruction. Dr Lawrence E. Young (Rochester, N. Y.) described some of his recent work with immune antibodies in hemolytic anemia and the production of auto- and iso-agglutinins in dogs. Dr William Dameshek (Boston) discussed abnormal agglutinins and their presence in acquired hemolytic anemia, the differentiation of acquired hemolytic anemia from the congenital types by serum antibody determinations, and the correlation of the presence of antibodies with a diminished survival time. He also pointed out that the antibodies of an abnormal type could be found in the hemolytic crisis of congenital hemolytic jaundice. In addition he presented observations of the reticulocytopenia and pancytopenia occurring in cases of hemolytic crisis, indicating possibly a hyperactivity of the spleen with resultant marrow inhibition and maturation arrest. The spleen in hemolytic anemia might have 3 functions: phagocytosis, inhibition, and antibody production. Observations in a recent case of hemolytic anemia associated with chronic lymphatic leukemia were cited, in which the picture of excessive blood destruction and of antibody formation were abruptly terminated following splenectomy, indicating that the spleen might well be a source of antibody production.

The meeting closed after 11 P. M. It was decided that the organization should be continued and that another meeting be held at approximately the same time next year. It was also decided that the group would continue on a very informal basis and that participation by anyone interested in the field of hematology would be invited. The round table type of discussion seemed to be in greatest favor with the audience, but it was decided that the exact type of program for the coming year would be decided upon by the committee.

MEETING OF FLORIDA ASSOCIATION OF BLOOD BANKS

A meeting of the Florida Association of Blood Banks was held in Miami, Florida on May 7-8, 1948. This meeting, sponsored by the Dade County Medical Association, was organized by Dr. John Elliott, Director of the Blood Bank and of the Medical Research Foundation of Dade County. A large number of workers in the field of blood and blood substitutes was invited to participate.

Dr. Alexander S. Wiener (Brooklyn, N. Y.) discussed the heredity of the Rh blood types and gave a clear exposition of his genetic theories and nomenclature in that field. Dr. Philip Levine (Raritan, N. J.) discussed the Rh factor with particular reference to the CDE nomenclature of Race and Fisher and disagreed sharply

with Dr Wiener's viewpoints Dr Ernest Witebsky (Buffalo, N Y) described his "9 drop test" for antibodies in the blood of the infant with erythroblastosis, and in addition made other observations regarding the use of antibody determinations in the mother for the detection of the presence or absence of erythroblastosis in the newborn infant Dr Louis K Diamond (Boston) described his technic for exchange transfusion in the treatment of erythroblastosis, pointing out the various advantages of the umbilical vein canalization method with the use of plastic catheters The mortality figures over a period of 20 years were impressive, indicating that with the newer technic, 90 per cent of infants with erythroblastosis may show complete recovery

Dr Virgil H Moon (Philadelphia) described his investigations in shock under various conditions and pointed out the fallacy of the term "lower nephron nephrosis" He advised the use of the term "tubular nephrosis" for the degenerative changes occurring in the kidneys under shock

Dr John Scudder (New York) described the technics in use in the Burn Clinic of the Presbyterian Hospital, pointing to the necessity for plasma and whole blood transfusions to maintain blood volume and blood counts He also emphasized the necessity for a "Burn Team"

Dr William Dameshek (Boston) gave a general discussion of anemia, its diagnosis and treatment, including recent investigations of the antibodies in association with hemolytic anemia Dr Louis Pillemer (Cleveland, Ohio) described his work in the characteristics and purification of plasma proteins and his contributions to the chemical nature of complement Dr Elmer de Gowin (Iowa City) described the use of whole blood and plasma products, giving a general discussion of transfusion technics and blood banking

Captain Lloyd Newhauser (United States Navy) discussed blood bank procedures in the event of an atomic bomb explosion when, for example, five bombs might be liberated over a large center of population

The final two papers were presented by Dr John Elliott who described indications for blood plasma and red cell transfusions, and by Dr Robert Elman (St Louis) who discussed the use of amino acids as a means of supplying parenteral protein

AMERICAN BLOOD BANKS ASSOCIATION CONFERENCE

A meeting of the American Association of Blood Banks will be held Aug 26-28 in Buffalo, N Y, following a meeting of the International Hematology Society there The Association was organized in Dallas, Texas, Nov 19, 1947, to disseminate information relating to blood banking, to unite blood banks in times of disaster, to train personnel, and to promote similar services throughout the United States and its territories Membership is of two classes institutional, available to non profit, independent banks including those operated by A M A registered hospitals, and individual, available to any person interested in blood banking Requests for applications or information may be addressed to Miss Marjorie Saunders, LL B, Secretary, American Association of Blood Banks, 3301 Junius Street, Dallas

IN MEMORIAM OF DR. HANS HIRSCHFELD

When I met Hans Hirschfeld for the first time, he was already numbered among the leading hematologists of the world. His rise had been difficult, since he was a pupil of Pappenheim, whose pithy criticism spared no one. Thus Hirschfeld had to obtain his place in the sun by fighting in the shadow cast by his great master, and he owes his reputation to his own scientific importance. It would be carrying coals to Newcastle to enumerate his numerous morphologic, clinical, and experimental works and try to appreciate their importance. He was much too modest and always harried by critical considerations, he disdained to lay stress upon his opinions, feeling sure that their correctness would be proved. He contended himself with expressing them, and he examined conscientiously every objection with which he was confronted.

When I went to see him in Berlin after my release from the Dachau Concentration Camp in 1940, I found him in back premises in a little room, almost squeezed in by his many books. He had been forced to quit his situation at the Cancer Institute of the Charité Hospital. He was allowed to attend only Jews, and had been eliminated from the editorship of the *Folia Haematologica*. Since the establishment of that journal by Pappenheim, Hirschfeld had labored for the perfection of that work under the greatest of sacrifices, and, after the shock of the first world war, had quickly regained for it its original international reputation. It was a grievous blow to him when his successor, devoted to national socialism, turned him away. Nevertheless, he uttered no word of complaint. Menaced most seriously in his existence, banished, the threatening cloud of the persecution of Jews ever harrying him and his family, Hirschfeld was an afflicted but by no means a broken man. No, he was a man who still took the liveliest interest in science and research. A presentiment that there would be no meeting again hovered over our last conversation and farewell. Afterwards we wrote one another several times. Then, the greetings on postal cards, signed only by an 'H,' failed to appear.

In the summer of 1945, a letter from Mrs. Hirschfeld informed me that her husband had died in the ill-famed Auschwitz Concentration Camp.

No tombstone adorns his grave. Even a last place of rest was begrudged him, who had worked so restlessly for the welfare of mankind. His works are a lasting monument to him. Those who knew him know what we lost by his death. He will ever remain a bright example to them of physician and man.

A. HITTMAIR, M.D.

BOOK REVIEW

La Maladie Hemolytique du Nouveau-Ne (Hemolytic Disease of the Newborn) By M BESSIS Paris, Masson & Cie, 1947, 248 pp

The physical isolation imposed by the Nazi regime on Europe during the period of 1939-1945 resulted simultaneously in a barrier to the ready exchange of scientific ideas. This volume, then, is all the more remarkable in that within the short space of two years, its author was able to read the voluminous literature on the subject of the Rh factor, adapt its specialized technics in his laboratory, and carry out clinical and experimental research on several aspects of the problem of diagnosis, pathologic physiology and treatment of Rh incompatibility and to organize his experience into this excellent summary.

The book is fundamentally a critical summation of the currently available knowledge of the Rh factor and its etiologic role in hemolytic disease of the newborn. It has the excellent qualities of careful organization, a clear manner of exposition, completeness without being overburdened with unnecessary chaff, and careful scrutiny of the various theories purporting to explain the mechanism of action of Rh incompatibility. The opening chapter is devoted to a discussion of blood groups and red cell antigens in general. This is followed by a description of the clinical, hematologic and pathologic findings in hemolytic disease of the newborn, weakened somewhat by the occasionally poor quality of the photomicrographs used as illustrations. An interesting discussion of some of the fundamental physiopathologic mechanisms of this disease is then presented, in which the author details and discusses his own work in this field, and the didactic sections of the book conclude with a discussion of treatment. One of the most helpful sections is the appendix, in which the author details methods of interrogation, blood grouping and performance of various diagnostic serologic examinations.

This book was expressly written to acquaint French speaking physicians with the latest developments in the field of Rh incompatibility. However, it is so well compiled and critically presented that all other physicians who read French will profit by it.

INFECTIOUS MONONUCLEOSIS

By SIR HENRY TIDY

EPFIEFFER, a pediatrician of Vienna, gave in 1889 the first clear description of the disease which we are here discussing, under the title Drusenfieber or glandular fever. He recognized that it was infectious and occurred in epidemics, described accurately the course of the enlargement of the cervical glands in young children, though he denied that other glands were involved, and stated that the glands never suppurated and that the prognosis was uniformly favorable.

Other observers in Germany quickly reported epidemics. Spread of its knowledge was somewhat slow but Park West (1896) reported an epidemic in America and Dawson Williams (1897) in England. The disease appeared to be successfully launched, but the diagnosis in sporadic cases rested on rather indefinite clinical features. It soon became confused with septic infections, and rapidly fell into disfavor. By 1900, it was practically dead. No mention of it appears in the Medical History of World War I, although information subsequently collected proves that it was not uncommon. It remained in suspended animation until 1920.

It is remarkable that during a period of thirty years, covering rapid developments in the knowledge of hematology, there should have been no systematic examination of the blood in a condition characterized by enlargement of lymphatic glands and often by enlargement of the spleen. To this lack of observation there is one exception. J. E. Burns, in 1908, fully described the lymphocytosis in two epidemics which he diagnosed as glandular fever, and published a well-documented report. The communication was completely overlooked and I was unaware of its existence until it was quoted by Bernstein (1940) in his monograph. Priority for the recognition of infectious mononucleosis clearly belongs to Burns.

Nevertheless, the establishment of the hematologic features of the disease did not come for practical purposes until 1920. Sprunt and Evans, in November 1920, published their observations on transient mononucleosis recorded in a series of six young adults during the previous six years. They recognized that the condition was infectious, observed the general glandular enlargement and gave an accurate though brief description of the various types of cells in the blood. They were clearly unaware of the existence of Pfeiffer's glandular fever, and thought they had discovered a new disease—a very venial mistake—and named it 'infectious mononucleosis'.

Authoritative articles soon followed. Longcope, in 1922, described fully the clinical aspects. He noted the long febrile period which might occur, and suggested the possibility of encephalitis in one case. Downey and McKinlay, in 1923, gave a complete description of the cells, beautifully illustrated, to which nothing effective has been subsequently added.

Meanwhile, Morley and I, in June 1920, recognized the existence of a transient lymphocytosis in the case of a boy whom we diagnosed as suffering from glandular fever, and we reported it with other evidence at a meeting of the Royal Society of Medicine in December 1920. At that time we were unaware of the article by Sprunt and Evans, but our attention was called to it when our article was in type and we formed the opinion that it was the same entity. In the course of the next few years, I saw a number of epidemics in boys' schools in England, and also cases in adults.

The recognition of the identity of infectious mononucleosis and glandular fever was not immediate in America, though Longcope used both terms in 1922, but it was probably general by 1925. The material on which the observations were based in America was predominantly from college students about the ages of 18 to 24 years, while in England it was supplied by resident preparatory school boys of 8 to 14 years. Although any type of the disease may occur at any age, there are considerable differences, when numbers of individuals are involved, between the clinical manifestations in the two age groups, the glandular enlargement being more marked at the younger ages. These factors no doubt account for the difference in nomenclature, for the disease is invariably known as infectious mononucleosis in America while in Britain it is generally named glandular fever. On the continent of Europe, the disease in young boys is now frequently described as "Pfeiffer's glandular fever" and that in adults as infectious mononucleosis, the identity of its infection in the two groups being accepted.

Neither resident college life nor resident preparatory schools are a part of the educational system in Europe outside Britain, and the recognition on the continent of a recoverable mononucleosis (other than that of whooping cough) was based on a different type of material, garbed in entirely other guise from that presenting in America and England. Deussing, in 1918, reported a series of cases with transient absolute lymphocytosis under the title "Über diphtherieähnlicher Anginen mit lymphatischer Reaction" (Angina resembling diphtheria with a lymphatic reaction). But it was a communication by Schultz in 1922, to the Congress for Internal Medicine on 'Monozytenangina' which first attracted attention to the subject. Both communications were based on the same type of material, being in regard to patients admitted to a hospital for communicable diseases who had membranous tonsillitis in which no diphtheria bacilli were found and in whom recovery followed without the injection of antitoxin.

The continental authorities went astray from the start. They were obsessed with the idea that the development of the lymphocytosis was due to a constitutional peculiarity of the patient resulting in a 'lymphatic reaction' and that the same angina in other individuals would result in a polynucleosis. The possibility of infection was scarcely considered. Secondly, they embarked on a tedious and sterile dispute amongst themselves covering many years as to whether the cells were monocytes or lymphocytes. They failed to recognize that both types of cells were often present at the same time and that either type might predominate at different periods in the same patient. Not until Glanzmann's monograph in 1930 did they admit that monocytic angina was a manifestation of infectious mononucleosis and recognize the influence of an infective factor as opposed to a constitutional diathesis.

The definite differentiation of monocytic angina from diphtheria was a clinical advance of importance, and it is somewhat surprising that so little notice was taken of it in American and British literature. The identity of monocytic angina with infectious mononucleosis was accepted without discussion by the specialists on communicable diseases, but its existence was certainly not generally known to the profession in Britain, even to the commencement of World War II. A brief clinical description of this type follows.

Monocytic angina or the anginose type of infectious mononucleosis is characterized by the development of a tonsillar membrane or of ulceration. The membrane in typical cases is indistinguishable in appearance from that of diphtheria, although it is a true membrane, and it often forms very rapidly. Edema of the neck and tenderness of the enlarged cervical glands is common but suppuration is very rare. Edema of the fauces causes great discomfort and anxiety, but in spite of this and the high temperature, the patient does not appear to be severely toxic nor does he become so, although the membrane may persist for several days or more than a week before separating, after which the symptoms improve with surprising rapidity. There is a previous period of slight malaise for two or three weeks with increasing sore throat, and some glandular enlargement may or may not have been observed.

There is no proof that the disease is infectious at this stage or that it spreads in this form, although a number of cases may occur in a unit of young adults. It is possible that the angina is a complication connected with the leukopenia which is often present initially, before the mononucleosis develops.

An extensive epidemic in England in 1930 was characterized by the severity and long duration of the attacks and by the high proportion of adults involved. During an initial febrile period which might last several weeks, the constitutional symptoms in this type are often suggestive of typhoid, and the characteristic features of infectious mononucleosis absent. Glandular enlargement develops late and is rarely of any great extent. The blood at the onset may show a definite polynucleosis. In prolonged cases, this may be observed to subside and for a period the blood count may be strictly within normal limits or passing to a leukopenia. The mononucleosis tends to develop about the time of the glandular enlargement and with their appearance the constitutional symptoms improve, often very rapidly, and the patient becomes convalescent.

Sporadic cases of this type are not uncommon and one instance was included in Longcope's article in 1922.

Four groups of clinical manifestations have so far here been indicated: (1) Pfeiffer's glandular fever in children, characterized by rapid and visible swelling of the cervical glands and a short duration, (2) infectious mononucleosis in young males with a longer but milder febrile stage and comparatively slight glandular swelling, (3) monocytic angina, and (4) long febrile types with late and slight enlargement of glands.

This grouping was useful while the clinical features of the disease were being carefully studied, but the disease is apparently a single entity and every permutation and combination of the four groups occur. Milder cases often fall fairly clearly into one group, but this is rarely so for the severer forms.

THE BLOOD PICTURE

It is probable that mononucleosis develops in every case of infectious mononucleosis

All the blood-forming tissues are affected, myeloid, monocytic (or reticulo-endothelial) and lymphoid, but at different times and to different degrees and varying in different cases and indeed in the same case at different stages. The effect on one system may be decreasing while on another it is increasing, thus producing the rapid changes in the blood picture which is so characteristic of the disease. The sequence of the changes is best observed in the long severe febrile cases, but unfortunately the diagnosis is rarely made in the early stages.

The myeloid system is earliest involved, but less constantly or severely and for a shorter time than the other systems. In mild cases, there may be no change in the circulating myeloid cells, but in severer forms an initial polynucleosis, such as 15-20,000 leukocytes with 75 per cent polynuclears, is not infrequent. This initial polynucleosis is a common cause for the diagnosis being overlooked. Polynucleosis is always transient and initial and never develops during the course of the attack. The rise of the mononuclear reaction may overlap the fall of the polynuclear cells, but in the more severe forms this reaction is delayed and the blood count becomes within normal limits and may remain so for two or three weeks or more, or may fall further to a leukopenia before the mononucleosis appears. Leukopenia is fairly common at the onset or during the course of severe cases before the mononucleosis develops. It is mainly due to granulopenia but even the lymphocytes may fall. In milder clinical types a mononuclear reaction may be present at the first examination or within a few days of onset.

The monocytic and lymphocytic reactions overlap, but the monocytic system subsides first and a pure lymphocytosis is finally left. So rapidly may alterations take place in the types of white cells and their number and so great are the differences in different cases that no single blood picture is exclusively typical of the disease. But most characteristic during the active stages is the presence simultaneously of various types of mononuclear cells, particularly with a high incidence of monocytes, an appearance rarely seen in any other disorder of the blood.

HETEROPHIL ANTIBODIES

Paul and Bunnell (1932) made the curious discovery that heterophil agglutinins develop in high titer in human serum in infectious mononucleosis and in no other disease, with some unimportant exceptions. The development of heterophil antibodies and the technic of estimation will not be discussed.

Important questions which arise are at what stage does the reaction become positive, and in what proportion of cases is it positive, and does a negative reaction exclude infectious mononucleosis?

In the common mild types the reaction is frequently positive at the first examination, which is usually four or five days after the onset. If the examination is earlier, the test may be negative or indefinite, the titer rising in the next few days. Owing to the certainty with which the diagnosis can be made on clinical and hematologic grounds, the test is not always repeated. Nevertheless, in these circumstances the reaction is positive in nearly 90 per cent.

But in the severer febrile forms the reaction may remain negative during several weeks of pyrexia and constitutional disturbances, and become positive about the same time as the mononucleosis and glandular swelling develop. It is striking how often the constitutional symptoms rapidly ameliorate within a few days of the rise in titer. Thus, the development of a positive reaction is related to the end of an attack rather than to the onset, and it may well be connected with the development of immunity, as Himsworth (1940) suggested. On more than one occasion, I have known the reaction to become positive for the first time during a relapse.

The titer has no constant relationship to the severity of the disease, the extent of the glandular swelling or to the degree of lymphocytosis. The time during which a reaction remains positive is very variable, but little more is known. The titer may fall from a very high dilution to negative in the course of a few days. In ordinary mild cases, it may become negative within two weeks of recognition, but it often persists for several weeks and has been found still positive after several months.

The significance of a negative test especially arises in epidemics in which all results are reported as negative, and in individual cases in which the test is repeatedly negative. The question arises whether or not there are two types of infectious mononucleosis, giving respectively positive and negative reactions. There is nothing inherently improbable in the existence of two viruses, but until we know more about heterophil agglutination, the evidence must be regarded as inconclusive.

I agree with the opinion of Paul and others that a positive reaction is proof of infectious mononucleosis and a negative reaction does not exclude it.

NEUROLOGIC MANIFESTATIONS

The neurologic manifestations of infectious mononucleosis have attracted attention recently and quite a number of cases have been recorded in the last few years. It is obvious that the presence of infectious mononucleosis in similar cases must previously have been overlooked. The existence of encephalitis was suspected by Longcope (1922) and by Glanzmann (1930) but the first clear descriptions of neurologic features were given by Epstein and Dameshek (1931) and by Johannsen (1931). The clinical pictures are extraordinarily varied and bizarre, and no two cases appear to be quite similar. The brain (encephalitis), meninges, cord, cranial nerves and peripheral nerves may be affected, either separately or in combinations or sequences. There is no constant order in which the ordinary manifestations of infectious mononucleosis and the neurologic symptoms respectively develop, or in their comparative severity. The glandular enlargement, lymphocytosis in the blood and in the cerebrospinal fluid, and meningeal or other neurologic symptoms may develop and subside simultaneously, as in Epstein and Dameshek's case. In other cases, the infectious mononucleosis may run its course and subside to be followed by nervous symptoms, lymphocytosis in the cerebrospinal fluid and a normal blood picture. Or again the symptoms of a benign lymphocytic meningitis may be subsiding before the features of infectious mononucleosis appear. In this last group the blood count may show an initial polynucleosis even with a high mononucleosis in the cerebrospinal fluid.

The symptoms of benign lymphocytic meningitis are exactly reproduced in certain of the cases. It is also noteworthy that in the more severe neurologic forms, the blood changes tend to be late and the glandular swelling slight as with other severe types of infectious mononucleosis.

The heterophil agglutinins have been estimated in all recorded cases since 1938 and the test always has been positive in the blood at some stage with the exception of two cases in sisters (Thelander and Shaw 1941), but it has never been positive in the cerebrospinal fluid. Observers might naturally hesitate to attribute to infectious mononucleosis neurologic symptoms with negative agglutination.

Recovery from neurologic manifestations takes place with extraordinary rapidity. A comatose and paralyzed patient with an extensor-plantar response may be apparently normal mentally and physically in three days. The question of encephalitis requires further observation. Severe headache is the commonest symptom in neurologic cases and is also an occasional complaint in ordinary types. Children and adolescents may take a surprisingly long time, six to twelve months, to recover their usual powers of concentration and application after a simple attack although apparently physically normal. It is possible that this is a sequel of encephalitis.

ASSOCIATION WITH JAUNDICE

Jaundice is now not uncommon at the onset or during the course of the severer forms but the association has become frequent only in the last ten or twelve years. It was not recorded in the epidemic in England in 1930, but in 1935 and 1936 many cases were observed in St. Thomas's Hospital (Tidy 1937) and it is now a recognized complication. When occurring at the onset, the jaundice is often of considerable severity and there is nothing to distinguish the clinical condition from an ordinary infective hepatitis. As the jaundice subsides, the pyrexia persists and the diagnosis of infectious mononucleosis often follows the discovery of lymphocytosis in a routine blood count or the observation of some glandular swelling, which occasionally is present at the onset.

Jaundice adds the symptoms of infective hepatitis to the symptoms of infectious mononucleosis but does not appear otherwise to affect the course. Jaundice is rarely severe when developing later in the illness. Whether the jaundice is due to a separate virus cannot at present be determined.

DIAGNOSIS

Possible errors in diagnosis are numerous and mistakes in practice are not uncommon, but with the transitory nature of ordinary attacks they usually settle themselves without important consequences. They will not be considered seriatim.

In the severer febrile forms, there may be no means of establishing the diagnosis for several weeks. This may also apply to onset with jaundice or with neurologic symptoms. The possibility of infectious mononucleosis as the essential factor in some cases of benign lymphocytic chorio-meningitis should be borne in mind. The blood changes should not cause difficulty in differentiation from leukemia when the patient is seen in the acute stage. In acute leukemia, the toxic symptoms are always severe.

An occasional but extremely difficult diagnosis may be caused by the rare slowly-progressive chronic lymphoid leukemia. In the earlier stages, there are periods of exacerbation with pyrexia and moderate glandular swelling. The lymphocytes for several years may be only at the upper limits of normal. They gradually creep up and the diagnosis, long suspected, slowly becomes confirmed. Diagnosis is especially difficult when it is asked for on a patient some months after a pyrexial attack with lymphocytosis considered to be infectious mononucleosis. Either lymphocytosis or glandular swelling may persist for several months after infectious mononucleosis, but if both features are present for six months the diagnosis must be considered to be in doubt, unless it has been fully established. I have watched three such cases, originally diagnosed doubtfully as infectious mononucleosis, gradually develop into fatal lymphoid leukemia or lymphosarcoma over periods of three to ten years.

THE PATHOLOGY OF INFECTIOUS MONONUCLEOSIS

By R. PHILIP CUSTER, M D, AND EDWARD B. SMITH, M D

INFECTIOUS mononucleosis is not so uniformly a benign self-limited disease as is generally regarded. Thomsen and Vimtrup³³ (1939) reported 6 fatalities in a series of 500 cases treated in the Blegdam Hospital in Copenhagen. Two of these were complicated by some other infection, but in 4 cases death occurred in uncomplicated infectious mononucleosis and was due in each instance to central respiratory paralysis. The 2 autopsies in this group were the first we found described in the literature. Jersild¹⁴ performed an autopsy on a patient who had had angina with sepsis, but who died of myocarditis attributed to infectious mononucleosis. Rupture of the spleen proved fatal in the patient examined by Ziegler¹¹ and fatal in 4 of the 7 cases of ruptured spleens in infectious mononucleosis which we reported.²⁹ The autopsy findings in 2 cases of Guillain-Barré syndrome associated with infectious mononucleosis were described by Ricker et al.²⁷ in 1947.*

Pathologic changes in the spleen following surgical removal for rupture have been reported by Atlee,² King,¹⁶ Darley et al.,⁷ Davis et al.,⁸ Milne,²¹ Vaughan et al.,¹⁸ and Smith and Custer.²⁹ Lymph nodes removed during the active stages of the disease were described by Gall and Stout¹² who included a review of the literature up to 1940. Moeschlin²⁴ presented his findings on aspiration biopsies performed in 3 cases (puncture of lymph nodes in all 3, of sternum in 2, and of spleen in 1). The bone marrow was erroneously described by Freeman,¹¹ but Nordenson,²⁵ and Limarzi, Paul and Poncher¹⁷ have given accurate accounts of the changes in this tissue. A biopsy of the liver performed at the time of splenectomy was illustrated by Davis et al.,⁸ and aspiration biopsies have been discussed by Kilham and Steigman,¹⁵ van Beek and Haex,³⁷ and Bang and Wanscher.³

The aggregate of the findings in this group of scattered case reports is in essential agreement with our observations in the following series, although with few exceptions the descriptions have been incomplete and the tissue changes inadequately illustrated. Moreover, the diagnostic value of histologic appearances in the lymphatic organs has usually been underestimated. The purpose of this paper is to present as nearly a complete pathologic picture of infectious mononucleosis as possible.

MATERIAL

This study was based on the following material, most of which was observed while the authors were on duty at the Army Institute of Pathology during the recent war.

Autopsies
Lymph node biopsies

9
100 plus

From the Laboratories of the Presbyterian Hospital in Philadelphia, and the Army Institute of Pathology, Washington, D. C.

* These are our Cases 1 and 2 which we retained in our series because Ricker et al. gave attention more particularly to the neurologic features.

Bone marrow aspirates	25 plus
Bone marrow biopsies	2
Extirpated ruptured spleens	3
Tonsillar tumor	1
Liver biopsy	1
Skin biopsies	2
Causes of death in the fatal cases were as follows	
Spontaneous rupture of spleen	4 (*)
Guillain-Barre syndrome	2
Nasopharyngeal hemorrhage	1
Laryngeal edema	1
Airplane accident (convalescent case)	1

PATHOLOGIC FINDINGS

Repeated reference will be made to the atypical or abnormal lymphocyte, the so-called infectious mononucleosis cell. We described this cell in a previous paper²⁹ as follows: "When stained lightly with hematoxylin and eosin in thin sections, it varies from 12 to 15 microns in diameter, occasionally larger, and is round except when distorted by crowding. The cytoplasm is homogeneous and faintly acidophilic. The centrally or eccentrically placed nucleus is sharply delineated by a thin membrane which blends with the marginal chromatin particles, chromatin is irregularly distributed to lend a mottled appearance, and it occasionally forms angulated bars. Indentation and folding of the nuclei can be demonstrated in relatively few cells. It is virtually impossible to determine in the sectioned material whether a true nucleolus is present or not, nor could "fenestration" be evaluated. We regard these cells as atypical or abnormal lymphocytes, closely related to, if not identical with, those found in the peripheral blood."

Following common usage we have employed the terms "infiltration" and "infiltrate" with reference to the presence of normal and atypical lymphocytes in connective tissues and as perivascular collars, i.e., situations where they are not normally found. We regard the majority of these cells, however, as of local origin and probably derived from pre-existing cells of the reticulo-endothelial system.

Hematopoietic System. *Lymph nodes* were usually but not invariably enlarged and displayed a variety of histologic appearances. In some instances, follicles were well preserved (fig. 1) and frequently assumed rather striking proportions (this is probably a transient phase). The structure of the follicular centers was not significantly altered except for a scattering of abnormal lymphocytes, histiocytes often contained cellular debris, and mitotic figures were common findings. In nodes such as these, the sinus structures were well preserved and contained varying numbers of normal and abnormal lymphocytes (fig. 2). The medullary cords were richly cellular and the same lymphocyte admixture was noted here. In a lesser number of cases the architectural pattern of the node was blurred, follicles being inconspicuous or even absent, and the sinus tracery was obscured as result of lymphocytic and reticulo-endothelial hyperplasia (fig. 3). This change was occasionally so striking as to

* The immediate causes of death in these 4 cases were hemorrhage (2), postoperative pulmonary embolism (1), blood transfusion reaction (1). In 3 other cases, the ruptured spleen was removed and the patients recovered.

FIGS 30-31 (See p 847)

FIGS 32-33 (See p 847)

FIG 1 LYMPH NODE A representative field from a node in which the general pattern was preserved. The follicle illustrated is rather poorly defined, but shows active proliferation in the follicular center and lymphocytic hyperplasia in the periphery. The sinusoid in the upper left is choked with normal and atypical lymphocytes. Reticulum cell outcropping is noted in the lower right, and the trabecula to the right displays a lymphocyte reaction ($\times 200$).

FIG 2 LYMPH NODE A medullary cord at higher magnification presents hyperplasia of lymphocytes, reticulum cells, and lining endothelium of a sinus. The sinus contains normal and atypical lymphocytes, one of the latter lying outside of the sinus in the upper center ($\times 1000$).

FIG 3 LYMPH NODE An extraordinary hyperplasia observed in a node removed during the peak of the illness. There is a striking hyperplasia of reticulum cells and abnormal lymphocytes to a degree that the entire nodal pattern is virtually obliterated to give the impression of a malignant lymphoma. The sinus tracery is preserved, however, marked by compact circumscribed aggregates of small lymphocytes ($\times 200$).

FIG 4 LYMPH NODE Higher magnification of the node shown in Fig 3, emphasizing the resemblance to a malignant lymphoma of the reticulum cell type. True nucleoli are small and not so conspicuous as irregular chromatin clumps and angulated bars. Mitoses are plentiful, but never atypical ($\times 1000$).

FIG 5 LYMPH NODE Section through periphery showing an afferent lymph vessel on the left, the lumen containing large numbers of normal and abnormal lymphocytes. The peripheral sinus of the node proper (right center) is also distended with round cells, and the capsule has virtually lost its identity by virtue of the lymphocyte reaction in the connective tissue, this is somewhat more marked than is usual ($\times 200$).

FIG 6 LYMPH NODE Section through hilum disclosing increased cellularity of the interstices and packing of efferent lymph channels with lymphoid elements, even more marked than one finds in the capsule ($\times 200$).

FIG 7 BONE MARROW There is a moderate granulocytic hyperplasia and a relative immaturity of the cells of this series. The small round cells shown in the picture are erythrocyte progenitors. Megakaryocytes are increased in number in proportion to the granulocytic hyperplasia. No lymphoid aggregate are present ($\times 1000$).

FIG 8 SPLEEN View at low magnification demonstrating a blurred pattern except for prominent subcapsular blood sinuses, the sinuses usually contain clumps of normal and atypical lymphocytes. The capsule and trabeculae show dilution and partial dissolution by reason of lymphocytic infiltration. In the lower right is a small, poorly defined Malpighian follicle, in other cases the follicles are large with prominent germinal centers ($\times 30$).

FIG 9 SPLEEN A stage in the dilution and dissolution of trabeculae as result of lymphocytic infiltration (presumably metaplasia of the trabecular connective tissue) ($\times 200$).

FIG 10 SPLEEN Subendothelial lymphocytic zone in trabecular veins ($\times 200$).

FIG 11 SPLEEN Adventitial lymphocytic reaction around intratrabecular artery ($\times 200$).

FIG 12 TONSIL Extensive necrosis with small island of residual lymphoid tissue. Necrosis of this degree is infrequent and follows ulceration and secondary infection. Lack of neutrophil response is common but inconstant ($\times 200$).

FIG 13 TONSIL Section through tonsillar bed discloses a marked lymphocytic reaction in the capsule (right) and in the interstices of an adjacent mucous gland (left) ($\times 200$).

FIG 14 TONSIL Section through a rapidly developing unilateral tonsillar tumor occurring during the acute phase of infectious mononucleosis. As in the lymph node illustrated in Figs 3 and 4, the histologic appearances simulate those of a malignant lymphoma (heterophil titre 1:1260, complete recovery) ($\times 1000$).

FIG 15 LUNG Peribronchial connective tissue and interlobular septum heavily infiltrated with lymphoid cells, the process involves interalveolar septa as well, rendering them thicker and more prominent ($\times 30$).

FIG 16 LUNG Extensive interstitial pneumonitis with virtually no intra alveolar exudate, the cellular reaction is entirely lymphocytic ($\times 450$).

FIG 17 LUNG Lobular pneumonia showing a rich fibrin network supporting a cellular exudate which is almost entirely of lymphoid type (In another case neutrophils predominated) ($\times 450$).

FIG 18 HEART Focus of normal and atypical lymphocytes in the interstices of the heart, in most instances such collections are perivascular in position. Slight edema is occasionally noted, but muscle fibers show no structural changes ($\times 800$)

FIG 19 STOMACH An increased number of lymphocytes in the tunica propria. There is also a conspicuous zone of round cells on the deep margin of the muscularis mucosa ($\times 100$)

FIG 20 ILEUM Peyer's patches are moderately hyperplastic (one case) ($\times 30$)

FIG 21 LIVER Capsule displays a lymphoid reaction similar to that observed in the spleen. The connective tissue appears to be losing substance in proportion to the increase in lymphocytes ($\times 350$)

FIG 22 LIVER Minimal lymphocytic infiltration of the periportal connective tissue ($\times 200$)

FIG 23 LIVER Marked periportal lymphocytosis, maximal in our series, simulating lymphoid leukemia. Lymphocytes are also conspicuous in surrounding sinusoids ($\times 125$)

FIG 24 KIDNEY Lymphocyte accumulations in the interstitium of the cortex ($\times 350$)

FIG 25 KIDNEY Perivenous aggregates of lymphoid cells in the boundary zone ($\times 200$)

FIG 26 ADRENAL Perivenous collections of lymphocytes indistinguishable from those frequently encountered in any routine autopsy series ($\times 350$)

FIG 27 THYMUS Adventitial reaction around a small artery, cut tangentially, predominantly atypical lymphocytes ($\times 750$)

FIG 28 PITUITARY Rather extensive interstitial collections of lymphocytes ($\times 350$)

FIG 29 MENINGES Pia-arachnoid showing patchy round cell aggregates, chiefly in the neighborhood of blood vessels ($\times 1000$)

FIG 30 BRAIN Lymphocytic infiltration in the periphery of a moderate sized blood vessel. There is edema of the adjacent tissue ($\times 200$)

FIG 31 BRAIN Perivascular cuffing and edema resembling that seen in various proven virus encephalitides ($\times 450$)

FIG 32 ANTERIOR SPINAL NERVE ROOT Marked perivascular lymphocytic reaction in a case of infectious mononucleosis with Guillain-Barré syndrome. Appropriate stains demonstrated degeneration of myelin and distortion of axis cylinders of the nerve fibers ($\times 200$)

FIG 33 SKIN There is hyperemia and edema of the corium associated with round cell reaction about vessels and appendages ($\times 100$)

simulate a malignant lymphoma (fig 4). Mitotic figures were abundant, but no atypical mitoses were observed. Connective tissue of the lymph node capsule, trabeculae, and hilum were more or less infiltrated with round cells, comprising for the most part both normal and atypical lymphocytes. The lymph sinuses in the hilum and perinodal tissue were usually crowded with similar cells (figs 5 and 6).

The spleen was invariably enlarged during the height of the disease as shown by the weights in our cases (table 1), the one normal weight of 150 Gm. in our series was in a convalescent patient who was accidentally killed. Milne²¹ mentioned a 970 gram spleen which ruptured and was successfully removed. The histopathology of the spleen has been recorded in detail in a previous article.²⁹ To summarize briefly, the capsule showed varying degrees of infiltration with round cells, consisting largely of both normal and abnormal lymphocytes. The trabeculae displayed dilution of the fibromuscular structure by a similar infiltrate (fig 9), not infrequently to the point at which complete dissolution occurred, the site of the trabeculae in such instances was marked only by the trabecular vessels. Follicles were usually widely spaced, in some instances being well preserved and hyperplastic, in others existing merely as ill-defined aggregates of small lymphocytes (fig 8). Occasionally, the eccentric arteriole was the only landmark. The blood

sinuses of the spleen contained more nucleated cells than erythrocytes except when there was marked congestion of the organ. The nucleated forms again were mostly normal and atypical lymphocytes. The red pulp likewise contained a predominance of these cell types. The changes in the blood vessels were twofold: first, an adventitial infiltration of lymphoid elements around intratrabecular arteries (fig. 11), and second, a similar subendothelial infiltration of the veins (fig. 10). These vascular findings have been noted also in leukemias and scarlet fever, occasionally in chronic malaria and acute fulminating infections. The subintimal infiltrate in veins has also been noted in allergic states, especially drug sensitivity, in which the patient survived more than twenty-four hours.

The *bone marrow* contained no abnormal cells apart from those in the circulating blood (fig. 7). The marrows were either quite normal or in some instances moderately hyperplastic. Hyperplasia was usually limited to the granulocyte series, although megakaryocytes occasionally seemed more numerous than usual. Unfortunately in our Case 4, characterized by purpura and thrombocytopenia, no bone marrow sections were obtained.

Respiratory System Mucous membranes of the sphenoid and ethmoid sinuses were available for study in 1 case. These appeared normal apart from a minor submucosal round cell infiltration which was nonspecific in character.

The *tonsils* were examined in 2 of the autopsied cases. Both showed areas of necrosis and a reaction of normal and abnormal lymphocytes, with a variable admixture of plasmocytes and neutrophils (fig. 12). The round cell infiltration was also noted in the peritonsillar tissue (fig. 13). In 1 case, the lingual tonsils and posterior pharyngeal wall were sectioned and displayed a similar cellular reaction deep in the striated muscle and around mucous glands of the tongue and pharyngeal wall. The *larynx* and *trachea* in another showed a like mononuclear cell infiltrate. In a patient who recovered, a rapidly growing tonsillar mass was regarded as a tumor and removed surgically. The tissue presented an amazing proliferation of lymphoid and reticulo-endothelial elements to a degree mimicking reticulum cell sarcoma (fig. 14), the surface was ulcerated and the obvious inflammatory reaction was limited to the margin of the ulcer.

The *lungs* displayed a variety of appearances. In 2 instances, there was a frank pneumonic consolidation, the cellular exudate in 1 was of the classic polymorphonuclear neutrophil type, while in the other it was made up almost exclusively of large lymphoid cells (fig. 17). Most cases showed a more or less marked exaggeration of the peribronchial and bronchiolar collar, and in some the round cell reaction extended along the intra-alveolar septa to simulate interstitial pneumonitis (figs. 15 and 16). Clusters of lymphoid cells were also noted in the subpleural connective tissue.

Cardiovascular System In 6 of the 8 cases in which the *heart* was examined histologically, aggregates of lymphocytes were sparsely distributed within the myocardium in the periphery of small blood vessels (fig. 18). They were also present in small numbers beneath the endocardium. In 1 case, the reaction was virtually negligible, and in another completely absent in the tissue studied. The myocarditis and pericarditis were minimal and unassociated with any necrosis of muscle or

serosal reaction respectively, except in case 3 where the cellular infiltrate was rather prominent in some areas. No real pericarditis was encountered. The aorta was examined in 3 cases. It was quite normal in 2 patients who died respectively on the thirteenth and thirtieth day of the disease, but in the third, who lived seventeen days, perivascular cuffing was seen about the vasa vasorum in the adventitia, the cells being the usual normal and atypical lymphocyte varieties.

As regards the *peripheral vessels*, one may generalize that, apart from the lymphoid tissues proper, the lymphocytic proliferation was either adventitial or subintimal in location, irrespective of the organ or tissue examined. The arterial involvement tended to be adventitial, whereas the venous was subintimal.

Digestive System The tunica propria of the *stomach* contained collections of lymphoid cells considerably in excess of normal (fig. 19) in 3 of the 4 cases examined. In the fourth case, a convalescent patient who had been ill 30 days, the reaction was equivocal. Sections of *ileum* from 4 cases proved difficult to evaluate because of the variable prominence of lymphoid tissue under normal circumstances in this age group. The lymphoid proliferation was distinctly abnormal in only 1 of these cases (fig. 20) and the cellular reaction was that of the lymphoid tissues elsewhere.

Liver changes were uniform qualitatively in the specimens examined from 7 autopsies and 1 biopsy. The capsule in most instances showed varying degrees of involvement similar to that seen in the spleen (fig. 21). The lymphocytic infiltration was most pronounced in the periportal connective tissue. Quantitatively, this reaction varied from hardly more than the usual lymphocyte collar (fig. 22) to a degree approaching that of lymphatic leukemia (fig. 23), with lymphoid cell aggregates extending into the adjacent lobular parenchyma. In these latter instances, there was an apparent loss of some of the peripherally placed liver cells, associated with minor bile duct proliferation. Necrosis of the liver parenchyma was not observed in our series, except in 1 case where portal vein thrombosis followed splenectomy. There was no evidence of biliary obstruction. Those cases showing a lymphocytic leukocytosis also displayed considerable numbers of round cells throughout the lobule, but within blood sinusoids. This more diffuse intra-lobular cellularity was augmented by Kupffer cell hyperplasia.

Perivascular lymphocytic collars were noted in only 1 of the 4 cases in which sections of the *pancreas* were available for study. The parenchyma of the organ was apparently normal.

Genito-Urinary System The *kidneys* were involved in 6 of 8 cases. In common with the other tissues, the lesion was confined largely to the periphery of blood vessels, notably the subintimal zone of the larger veins in the columns of Bertini (fig. 25). Aggregates of lymphocytes were also found in the interstices of the cortex (fig. 24). There were no alterations in the nephrons except in the case of a transfusion reaction, where a hemoglobinuric nephrosis (lower nephron nephrosis) was present.

The 2 sections of *urinary bladder*, 3 of *prostate*, and 2 of *testis* all presented interstitial foci of lymphocytes in the neighborhood of small blood vessels.

Endocrine System The *adrenal* was examined in 7 cases, 5 of which displayed clusters of normal and abnormal lymphocytes beneath the intima and in the periphery of the central vein (fig. 26) as well as in the capsule. The occurrence of lymphocytes

in the adrenal is so common in the average series of autopsies that it is difficult to evaluate this finding as related to infectious mononucleosis.

The lymphoid tissue of the *thymus* was not hyperplastic in either of the 2 cases examined, and the organs were not enlarged grossly. In one of the glands, there was a perivascular reaction in which abnormal lymphocytes were present (fig. 27), the findings in the other being equivocal.

Two of the 4 *pituitary glands* displayed prominent aggregates of lymphocytes in the interstices (fig. 28), a third showing a few such cells and the fourth being essentially normal.

Nervous System The central nervous tissues and peripheral nerves in our Cases 1 and 2 have been described in detail by Ricker et al.,²⁷ and adequately illustrated. In summary, the meninges were congested and edematous and contained moderate numbers of mononuclear cells (fig. 29). Occasional small perivascular hemorrhages were noted within the brain substance, as well as mild ganglion cell degeneration, occasionally with satellitosis. Changes in the spinal cord were minor, but cellular infiltration of anterior nerve roots was noted at all levels, particularly in the periphery of blood vessels (fig. 32). The myelin sheaths were swollen and disrupted. In 3 other cases, distinct perivascular cuffing with round cells had occurred in the brain (figs. 30 and 31) and in 2 of these the meninges were similarly affected. An additional case displayed no demonstrable involvement. Thus, in 5 of 6 cases there was evidence of a mild to moderate meningo-encephalitis, and in 2 a distinct peripheral neuritis.

Musculature Sections of voluntary muscle were examined in 2 cases, one appearing normal, the other showing lymphocytic collars in the periphery of small blood vessels.

Integument Two biopsies of skin revealed a relatively normal epidermis save for a lymphocytic infiltration of some of the rete pegs (fig. 33). The corium was rather edematous and hyperemic, and an infiltration of small and large lymphocytes was noticeable in the vascular peripheries.

CLINICO-PATHOLOGIC CORRELATIONS

We have shown that there are as many lesions of infectious mononucleosis as there are organs and tissues of the body, although the degree of involvement of each varies markedly from case to case. This is manifest clinically by the wide range of signs and symptoms listed in the many series of cases reported in the literature. We have selected Read and Helwig's²⁶ analysis of 300 Army cases to illustrate this, and to show that virtually all of the clinical features may be explained on the basis of demonstrable pathologic changes. Tables 2, 3 and 4 are taken directly from their article, although the items have been rearranged by systems to conform with the scheme used for our pathologic descriptions. In the following paragraphs, we will also add certain features of the disease not mentioned in Read and Helwig's series. It is interesting to note that most of the clinical manifestations of the disease serve to confuse rather than to clarify the diagnosis.

Hematopoietic System In view of the fact that hyperplasia of lymphoid tissue is the major and most consistent pathologic change in infectious mononucleosis it is

readily understood why enlargement of the *lymph nodes* and *spleen* are the most commonly observed physical findings. The rapidity with which the enlargement develops accounts for the tenderness of these organs. We have shown in a previous article²⁹ that the tense, swollen spleen of infectious mononucleosis is peculiarly liable to rupture because the capsule and trabecular are more or less diluted and sometimes dissolved by lymphocytic infiltration.

Erythropoiesis in the *bone marrow* in nearly all cases appears to be essentially normal, thus explaining the rarity of anemia in infectious mononucleosis. The cause of anemia in the few cases reported was not apparent, in other instances, the anemia was regarded as coincidental. Granulocyte components are either normal or increased in number, and may show some degree of immaturity and toxic granulation (Limarzi et al.) Study of cases with actual neutropenia has been inadequate to demonstrate any significant change in the marrow. Neutrophilic leukocytosis fol-

lowing rupture of the spleen or with associated pyogenic infection may occur very rapidly and demonstrates the responsiveness of the marrow, sometimes masking the original lymphocytosis

Minot^{22, 23} was the first to describe the striking thrombocytopenia with hemorrhagic purpura which occasionally complicates infectious mononucleosis and then regresses during convalescence. As Minot's²² case was observed before the heterophil antibody reaction had been described, he hesitated to make a precise diagnosis, but in view of recent reports^{18 20 30} there can be no doubt that this was infectious mononucleosis. One of our patients (Case 4) who died following rupture of the spleen had a condition of this type, but unfortunately bone marrow was not removed at autopsy. The only marrow study of the thrombocytopenic variant which we have found was reported by Dameshek and Grassi⁶ whose patient recovered after splenectomy, they described an increase in megakaryocytes which showed "greatly diminished platelet production."

Respiratory System The essential lesion in the nose and throat is lymphoid hyperplasia which may subside uncomplicated by secondary infection or necrosis and without undue discomfort. In other instances, however, ulceration supervenes with extension of secondary invaders to produce membranous pharyngitis, peritonsillar abscesses, and even Ludwig's angina. Epistaxis probably results from ulceration and necrosis of hyperplastic lymphoid tissue in the nose, tissue was not available for study in our Case 9 in which death was due to nasopharyngeal hemorrhage, so that we were unable to demonstrate this. However, in Case 6, there was actual gangrene of the tonsil and posterior pharyngeal wall, and in Case 1, necrosis of tonsils to a lesser degree. Occasionally the lymphoid overgrowth may be so exuberant as to simulate a malignant tumor, as in one of our patients who made an uneventful recovery.

Tidy³⁶ and Wintrobe⁴⁰ state that laryngeal obstruction is unknown, yet the cause of death in our Case 6 was edema of the glottis. Cough is probably due most commonly to tracheobronchitis, observed in the single specimen available to us, and to actual involvement of lung tissue which was slight in 5 of our 9 autopsies, prominent in 3, and absent in 1. It is interesting that 19 of Read and Helwig's²⁶ cases were diagnosed atypical pneumonia on admission, figs 15 and 16 make clear that interstitial pneumonitis actually can occur as a feature of infectious mononucleosis and would be indistinguishable clinically and by x-ray examination from the interstitial pneumonitis of atypical pneumonia, influenza, or even rheumatic pneumonitis. Similarly, the lobular pneumonia found in Case 9 can be linked to infectious mononucleosis only by the mononuclear exudate in the alveoli. The sometimes marked acceleration in respiratory rate is probably due to pneumonitis or pneumonia usually not recognized as part of infectious mononucleosis per se.

Cardiovascular System No symptoms referable to the heart are listed in Read and Helwig's²⁶ article. However, arrhythmias and tachycardia are known to occur. Wintrobe⁴⁰ mentions one patient in whom tachycardia and cyanosis became so pronounced that acute cardiac dilatation was suspected. Myocarditis was the stated cause of death in Jersild's¹⁴ case.

Electrocardiographic evidence of heart lesions has been reported. In Evans and

Graybiel's¹⁰ 4 cases the T waves were lowered or inverted in all leads suggesting pericardial involvement, with gradual return to normal during convalescence. Logue and Hansen¹⁹ record first degree heart block with prolonged P-R interval, while Candel and Wheelock's⁴ case had electrocardiographic tracings indicative of acute myocarditis.

We were unable to demonstrate pericarditis in our 9 cases, at most, there was a sparse sprinkling of lymphocytes in the subepicardial connective tissue no greater than that one frequently encounters in a series of routine autopsies. Lesions were found in the muscle, however, in 6 cases, doubtful in 1, and in Case 9 no heart sections were available for study. The foci were small in all but Case 3, where there were rather extensive residual areas of myocarditis at the time of accidental death thirty days after the onset of illness.

Digestive System It is virtually impossible to demonstrate an anatomic basis for the nausea, vomiting, and diarrhea occurring in a febrile illness. We did find lymphocytic infiltration of appreciable degree in the tunica propria of the stomach in 3 of 4 cases examined, and fairly marked hyperplasia of intestinal lymphoid tissue in 1 of 4 cases, this change being equivocal in 3. It is doubtful whether these observations are of clinical significance.

Abdominal pain and tenderness are probably due to rapid enlargement of the spleen, liver, and abdominal lymph nodes.

Physical examination of patients with infectious mononucleosis frequently discloses an enlarged liver. In our 4 cases in which figures were recorded, the organ weighed 1650 Gm, 2100 Gm, 2600 Gm, and 2738 Gm. The normal-sized liver was from a convalescent case, whereas the patient with the largest liver died from a pulmonary embolism five days after operation for ruptured spleen on approximately the thirty-fifth day of the disease. It should be mentioned that hepatomegaly is not usually a feature of the milder case.

Liver function tests reported by Cohn and Lidman⁶ in a series of 15 consecutive cases of proven infectious mononucleosis without jaundice gave evidence of liver damage; they found the thymol turbidity and bromsulfalein excretion tests of most consistent value. "There appeared to be a rough correlation between the severity of the disease and the degree of hepatic impairment." Their results were confirmed by DeMarsh and Alt⁹ in 19 additional cases. Jaundice is not a rare manifestation of infectious mononucleosis and provides further evidence of liver involvement. Changes in the liver in jaundiced cases as described by Bang and Wanscher³ do not differ from those in patients who have not been jaundiced. They found no reason to regard the jaundice as due to obstruction.

The liver lesion is essentially a periportal hepatitis. It is hardly distinguishable from liver changes in the milder cases of epidemic hepatitis as observed at biopsy. Necrosis of liver cells was observed in only 1 of our fatal cases, and was apparently due to portal vein thrombosis incident to splenectomy rather than to infectious mononucleosis per se. There may, however, be some slight loss of liver cells in the periphery of heavily infiltrated portal areas.

Genito-Urinary System Albuminuria is common, as in any febrile disease, leukocytes and red blood cells are not infrequent urinary findings, but casts are not generally seen. Gross hematuria was found in 6 per cent of Tidy and Morley's³¹ 270

cases, apparently occurring as an isolated phenomenon, it may also appear as part of the general hemorrhagic manifestations in the thrombocytopenic variant. The renal lesion of infectious mononucleosis is essentially an interstitial nephritis. As for the genitalia, uterine bleeding in the hemorrhagic form of the disease is the only symptom of which we are aware, in Dameshek and Grassi's⁶ case there was also a suggestion of a pre-existing hemorrhagic tendency.

Nervous System Although Read and Helwig²⁶ do not mention headache in their series, this is a very common symptom, often associated with blurring of vision and vertigo, and occasionally with stiff neck. Stupor, coma, delirium, and convulsions have been observed, as well as paresthesias, motor paralyses, and depression of the respiratory center. Two of our fatal cases presented the Guillain-Barré syndrome. A wide variety of neurologic signs has been reported.^{13, 27, 28, 32} The cerebrospinal fluid findings are variable, more frequently being normal, the pressure is sometimes increased, and a lymphocytosis of several hundred cells and increase in protein have been observed. The differential diagnosis between infectious mononucleosis and lymphocytic choriomeningitis may be difficult under such circumstances. Tidy³⁵ has attempted to relate the two diseases, but Viets and Warren³⁹ state that in lymphocytic choriomeningitis, all organs except the central nervous system are relatively normal, and describe "inclusion bodies" in ganglion cells, more extensive meningeal and perivascular lymphocytic infiltrations, perivascular hemorrhage, and "glial nodules."

We have demonstrated varying degrees of encephalitis, meningitis, or both, in 3 of 4 cases in which no symptoms referable to the central nervous system were recognized. However, one of these patients lost his life in the crash of an airplane which he was piloting during the convalescent period, and the disease may have been a factor leading to the accident. In our 2 cases presenting the Guillain-Barré syndrome, there was the additional involvement of spinal nerve roots but only minor ganglion cell changes in the cord proper, peripheral nerves were examined in 1 of these cases and showed lesions similar to those of the nerve roots.

Musculature Myalgia is an uncommon symptom, although we found myositis in 1 of 2 cases in which skeletal muscle was examined.

Integument Cutaneous eruptions of various types, usually morbilliform, are frequently encountered in infectious mononucleosis.³¹ Our 2 biopsies from such cases disclosed hyperemia, edema, and cellular reaction in the corium.

SUMMARY

This pathologic study is based on 9 autopsies and many biopsies in cases of infectious mononucleosis.

The gross changes were almost exclusively confined to enlargement of lymphoid tissues, especially the spleen. Nasopharyngeal lymphoid hyperplasia was constant, in one instance suggesting tumor. Other tissues presented no significant gross features related to the primary disease except for (1) rather consistent enlargement of the liver, (2) infrequent icterus, and (3) occasional cutaneous rash. Histologic observations revealed more or less generalized lesions resembling those of certain known virus diseases, notably perivascular aggregates of normal and abnormal lymphocytes. Reaction of this type inconstantly involved all tissues studied except

the bone marrow, here lymphocytes were virtually absent in sections, but were present in aspirated marrow because of dilution with peripheral blood

More specific changes were invariably noted in lymphoid tissues. The abnormal lymphocyte characteristic of the disease could be identified in thin, lightly stained sections. Lymph node reactions varied from a predominantly follicular hyperplasia to a blurred pattern simulating a malignant lymphoma, the latter was due to a lymphocytic and reticulo-endothelial proliferation in the medullary cords. The spleen displayed a lymphocytic infiltration in the thinned capsule and trabeculae, frequently dissolving the latter and rendering the organ liable to rupture. The pattern was partially effaced in most instances and the follicles widely spaced. Blood sinuses contained considerable numbers of normal and abnormal lymphocytes, and accumulations of these cells constantly cuffed intratrabecular arteries and lay beneath the intima of veins. Tonsils displayed ulceration and necrosis in several cases, and the lymphocytic proliferation closely resembled malignant tumor in a tonsil that enlarged rapidly.

A pneumonic exudate in 1 case was almost exclusively of round cell type, while in another the pneumonia was of the usual lobular type with a neutrophilic exudate. Small myocardial infiltrates which we noted probably explain the electrocardiographic changes described in infectious mononucleosis. Other findings of particular interest were the periportal lymphoid collars in the liver which sometimes attained the proportions seen in leukemia, and the presence of meningo-encephalitis in 4 of the 6 brains examined.

We believe that the majority of cells in the lymphocytic "infiltrates" of connective tissues and the perivascular collars are metaplastic rather than inwandering, i.e., that they are formed in situ and stem from cells of the reticulo-endothelial system.

ADDENDUM

Since this paper was prepared, our Case 3 has been reported separately by Allen and Kellner.¹ We have held the case in our series, however, as it lends strength to our tabulated findings.

CHRONIC INFECTIOUS MONONUCLEOSIS

By RAPHAEL ISAACS, M.A., M.D

IN A GROUP of 206 patients who had infectious mononucleosis, 53 had some symptoms which persisted for from three months to at least four years or longer. The syndrome included ease of fatigue, exhaustion, aching of the legs, weakness, depression, afternoon elevation of temperature (99.8 to 101 F), moderate splenomegaly, low blood pressure, low blood sugar, often low specific gravity of the urine, and the presence of infectious mononucleosis cells in the blood.

The 53 patients with the chronic symptoms included 22 males and 31 females. The ages ranged from 8 months to 60 years. There were 5 younger than 19 years, 20-29 years, 12, 30-39 years, 16, 40-49 years, 15, 50-60 years, 5. The 8 month old child showed unusual diarrhea ("dysentery") since birth, and examination of the blood showed infectious mononucleosis cells. The mother had acute infectious mononucleosis during pregnancy, one month before the birth of the child. Thirteen of the patients had the symptoms for from 3 to 6 months, 15 for 7-12 months, 3 for 17-18 months, 11 for one year, 8 from two and one-half to four years and 3 for at least six years. Some of the patients could give the exact date of the start of the symptoms, others within a month or so. Five gave the duration as "several months," "several years," "many years."

These patients had been sent in for study, with possible diagnoses of undulant fever, tuberculosis, Addison's disease, Hodgkin's disease, Rocky Mountain spotted fever, lymphosarcoma, hypothyroidism, menopausal syndrome, subacute bacterial endocarditis, neurasthenia and syphilis.

All of the group showed infectious mononucleosis cells in the blood. The red blood cell and leukocyte counts and hemoglobin content were within normal limits. The infectious mononucleosis cells were of the mature type, with deeply basophilic cytoplasm, staining the peculiar blue characteristic of these cells. The nuclei showed the streaky chromatin, with fenestrations, and were often indented. Occasionally one or more of the large forms found in the acute type were noted. The cells constituted 1 to 7 per cent of the total leukocytes, rarely higher. These cells had been grouped with the lymphocytes or monocytes by uncritical technicians.

In no case of the chronic group was the sheep cell (heterophile) agglutination titer above 1:64. Five patients showed persistent "positive" Kahn tests, characterized as "general biologic reaction," for one to six years.

The presenting symptom was always weakness or ease of fatigue. The patients said that their legs were weak and ached. The fatigue was usually present on arising in the morning, but occasionally developed late in the morning or during the afternoon. Some had symptoms suggestive of hypoglycemia. Others had mental depression, nervousness, ease of perspiration and dizzy or giddy spells on arising.

The fatigue appeared out of proportion to the physical data. The usual findings

were a slightly enlarged spleen about 14 to 16 centimeters, occasionally palpable on deep inspiration depending on the patient's body-build. The spleen could be outlined by direct percussion (not by the intermediate method) by using very light tapping. It could be demonstrated by x-ray examination. The enlarged spleen elevated the cardiac apex, while the patient was lying down, so that the cardiac tip was from 10 to 11 cm. to the left of the midline. On standing the apex lowered to about 9 cm. to the left of the midline.

The second feature noted in most of the patients was the comparatively low blood pressure. The systolic figures were from 95 to 105, occasionally as high as 115, with diastolic pressures of 56 to 70. This was significant, as most of the patients belonged to the older age group. There were no definite signs of myocardial or circulatory insufficiency, and there was usually no edema of the ankles.

In most of the patients who made observations on their temperature, there was an afternoon rise to 99.6-101.4 F. Rarely was it higher than this, but in some the elevation was so persistent that they had been diagnosed 'fever of unknown origin' or were suspected of having undulant fever, Hodgkin's disease or tuberculosis.

Most of the patients had some lymph nodes which were palpable, but never very large. Enlarged posterior cervical nodes were the most common. In many, the nodes were well within normal limits of size.

A number of patients had symptoms suggestive of hypoglycemia. Late in the morning there was a feeling of exhaustion, anxiety, increased perspiration. The blood sugar (fasting, after food, and at intervals after sugar ingestion) was observed in ten individuals. The fasting blood sugar showed levels of 33 to 70 mg per 100 cc. using a method in which most normal individuals showed from 80 to 110 mg per 100 cc. Isolated observations on other patients in the group showed levels of 80 to 95 mg per 100 cc. After ingestion of a meal or a measured amount of glucose, there was but slight increase in the height of the glucose curve (increased tolerance), and the fall was slow, although 3 individuals showed a lower level than the fasting level between three and five hours after the ingestion of the glucose.

The serum sodium, potassium and chlorine was within normal limits in these patients. None of the patients showed unusual pigmentation.

In 12 of the patients, low basal metabolic percentage had led their physicians to prescribe thyroid, without therapeutic advantage, however, as the abnormal fatigue persisted.

The only feature of the urine which was present in most of the individuals was a low specific gravity of individual specimens taken at random during the morning or afternoon. Values from 1.001 to 1.008 were common, and values higher than 1.010 were unusual in this group.

In 3 patients of the group being studied, although the onset was typical of acute infectious mononucleosis, material from lymph nodes had been obtained by biopsy. The sections were variously interpreted by different observers, and x-ray therapy was given over all the glandular areas by the patients' doctors. These patients later

had a recurrence of the glandular enlargements, and one was diagnosed as lymphosarcoma, one reticulum cell sarcoma and one Hodgkin's disease. They continued to show clear-cut infectious mononucleosis cells in their blood. The "lymphosarcoma" patient received intensive x-ray irradiation from several doctors, as well as "nitrogen mustard" until he died of emaciation. The results make one wonder if lymph nodes, injured or made more susceptible by infectious mononucleosis, may be made to show "malignant" characteristics after x-ray therapy.

In another group, 2 patients showed progressive enlargement of the spleen and were later classed as "Banti's disease." It is possible that some congestive splenomegalies may arise in this way.

In the differential diagnosis, undulant fever presents the most difficult problem. The various tests for degrees of immunity are not diagnostic of the disease, and a positive blood culture is not easily obtainable in the chronic form. The presence of infectious mononucleosis cells in the blood is a differential point, although an individual could have had both diseases. When the Kahn test was positive in these patients, it was of the "general biologic" type.

TREATMENT

Many therapeutic agents were tested without success. These included caffeine, amphetamine sulfate (benzedrine and dexedrine), strychnine, thiamine, atropine, multiple vitamin mixtures, thyroid, ephedrine and special diets. These substances produced no lasting effect, and often accentuated the nervousness. The most promising medicine appeared to be a preparation of adrenal cortical extract (cortalex). This was given in doses of 2 tablets (made from aqueous extract of 10 grams of adrenal gland) on arising in the morning. There was but little subjective improvement during the first week, but a definite feeling of well being developed during the second week and was quite definite during the third week. After this the medication was discontinued and the improvement usually continued. In a few patients it was necessary to increase the dose, or resume it after its discontinuance. Associated with the subjective improvement, there was a decrease in the size of the spleen. The changes in the blood pressure were slight.

The fact that the symptomatology is somewhat suggestive of adrenal insufficiency of the Addison's disease type, and that administration of adrenal cortical extract by mouth relieved the patients after the symptoms had persisted for long periods, suggests a possible mechanism for the fatigue during the chronic stage. There are apparently no data on the appearance of the adrenal cortex in this condition, and whatever damage is present must be reversible, if adrenal insufficiency is the cause of the symptomatology.

SUMMARY AND CONCLUSIONS

A group of patients is described in whom ease of fatigue, fever, splenomegaly, low blood pressure, low blood sugar, low specific gravity of the urine and the presence of infectious mononucleosis cells in the blood persisted for from three months to longer than four years after the initial attack.

Three of the group developed characteristics of lymphoblastoma and two showed the features of Banti's congestive splenomegaly.

The symptoms responded to treatment with a preparation of adrenal cortical extract.

The syndrome is apparently not uncommon and the intense, prolonged debility, together with the marked improvement after therapy with adrenal cortical extract, makes its recognition of great practical importance.

IS IT POSSIBLE TO TRANSMIT OR ACCELERATE THE DEVELOPMENT OF MOUSE LEUKEMIA BY TISSUE EXTRACTS?

By J ENGELBRETH-HOLM, M.D.

DURING the last ten years it has been reported from various laboratories that the injection of certain tissue extracts has been followed by accelerated development of spontaneous leukemia in mice, the disease presenting an increased incidence and (or) an earlier appearance in the experimental animals than in the untreated controls. Although these observations lack satisfactory confirmation, it seems desirable to review them here, and to record some supplementary investigations bearing on the same problem.

In the Year Book of the Carnegie Institute, New York, for 1937, MacDowell and collaborators described experiments in which monthly injections of embryonic tissue extract into mice of the strain C 58 (with a 90 per cent leukemia incidence) were followed by development of the disease in all of the 60 experimental animals at an earlier date than in the controls belonging to the same litters. The results were not reported in detail, nor was it stated whether the test has been repeated. Gorer, who tried to confirm this finding, states merely "Inoculations of embryonic tissue have had no noticeable effect on either the 'albino' or the 'black' leukemia."

In 1938, Engelbreth-Holm and Frederiksen believed they had transmitted mouse leukemia to young animals of the strain Aka by means of a cell-free extract of leukemic organs from mice of the same strain. The extract was prepared under anaerobic conditions reduced in a cysteine-cobalt-sulphate system as described by Pirie and Holmes. Injection of the extract was followed by the development of leukemia in 8 experiments out of 9, totalling 36 mice out of 179. The tests were carefully controlled in various ways. Thus, *aerobically* prepared extracts showed no effect in 5 experiments including 120 animals. Further, a minimum of 1000 cells was found to be necessary to secure a "take" in the ordinary way, it therefore seemed impossible that the "takes" in these experiments could have been due to presence of sufficient intact cells in the extract, since the latter had been centrifuged twice for fifteen minutes at 3,000 r p m. As a most deplorable fault, it must be noted that the extract was not filtered in these tests. Engelbreth-Holm later (in 1942) expressed the view that the findings in these experiments might have been a question of acceleration of spontaneous leukemia rather than of a transmission of the disease.

MacDowell and his collaborators (1939) tried to repeat the observations of Engelbreth-Holm and Frederiksen without success. Still more confusion however, was brought into the matter when, after control injection of the medium used for reduction (a cobalt-sulphate-cysteine solution), MacDowell found leukemia developing in 17 out of 20 mice only twenty-six to thirty-eight days later. Repetition of this experiment gave negative results.

From the University Institute of Pathological Anatomy, Copenhagen

These investigations have been aided by grants from the Anders Hasselbalch Leukemia Fond, the König Christian den Tiendes Fond and from the National League for Combating of Cancer

Finally, Gorer in 1939 reported a somewhat analogous observation. Inoculation into mice of a "nontaking" sarcomatous tissue appeared to increase the leukemia incidence from 6 to 39 per cent in all animals, and from 2 to 46 per cent in the males. Reinoculation brought about a still greater rise in incidence. Gorer inoculated a sarcoma from an albino strain into a black mouse strain. After repeated inoculations, leukemia developed in 7 out of 10 mice, whereas the spontaneous leukemia incidence was only 6 per cent. Gorer found that the leukemia did not develop until about one year after the inoculations, i. e., probably at the same age at which the disease will appear in untreated mice.

In an attempt to explain the results of our original experiments (Engelbreth-Holm and Frederiksen), new investigations along the same lines were performed during the years 1938-42. Our efforts, however, were no more successful than those of MacDowell. We did not observe any acceleration of the leukemia in mice belonging to the strain Aka after injection of an extract of leukemic organs prepared under anaerobic conditions. Repeated injections of such extracts were made in 25 mice belong to the strain Aka, a total of 17 injections being administered at intervals of two weeks. For control purpose, extracts of normal organs were injected into brothers and sisters of the experimental animals, but no effect was seen in either of the two series.

Likewise, MacDowell's experiments with the cobalt-sulphate-cysteine solution were repeated. Forty-eight Aka-mice were given 1 cc. of the solution, the mice at the beginning of the experiment were one month old, and the injections were administered every two weeks until they died spontaneously. In 23 out of these 48 mice, leukemia developed, but among their 44 untreated brothers and sisters, 23 cases of leukemia were found as well, the treatment, therefore, had had no evident effect.

No more did we succeed in accelerating other tumor types: leukemia and mammary carcinoma of the strain dlb. These experiments, comprising 38 and 15 mice respectively, were equally negative.

The most natural way in which to explain these rather capricious and mostly negative results was to assume that, despite the precautions taken, the spun extract in our 1938 experiments did contain a number of intact cells sufficient to secure "takes", this explanation still failed to account, however, for the fact that administration of *aerobically* prepared extracts did not give any "takes". In spite of numerous unsuccessful attempts to repeat our 1938 observations, and in spite of the controls having indicated that a few intact cells in the injected substance could not explain the development of leukemia, I initiated one more experiment in order to exclude the possibility that cells when suspended in the cobalt-sulphate-cysteine solution were more capable of "taking" than when suspended in a sodium-chloride solution as in the original control experiments.

Known numbers of leukemic cells, suspended partly in normal saline and partly in a cobalt-cysteine solution, were accordingly injected into series of mice. The result may be seen in table 1.

No explanation was achieved by these experiments, as suspension in the reduction solution had a definite effect in suppressing the "taking" capability of the

cells (a finding which was to be expected beforehand), leaving it, thus, still more improbable that our "takes" or "accelerated cases" in the experiments of 1938 could have been due to the presence of intact cells in the extract solution

In 1946, however, a paper was published by Silber in Russia, describing investigations which may possibly throw some light on these obscure questions, though it is necessary to await confirmation of the findings before reaching a final opinion. According to Silber, sarcomas induced in mice by 1,2,5,6-dibenzanthracene are transmissible by means of Berkefeld-filtered extracts of tumor tissue which has been treated according to the method introduced by Engelbreth-Holm and Frederiksen (dissection in a closed chamber filled with carbon dioxide, and suspension in a cysteine-cobalt system in order to prevent oxidation)

In 4 out of 5 experiments, Silber had "takes" in a total of 18 out of 114 animals. He makes it clear, however, that the takes occurred only when the substance had been prepared from very young tumors ("incipient" sarcomas), and, further, that the experimental animals required to be "sensitized" by "subcutaneous injection of 0.5 cc. of an oily solution of Dibenzanthracene containing 1 mg. of this substance in one liter of vegetable oil. This injection was administered 1-2 weeks before the test." Without this "sensitization" no takes were seen.

TABLE 1

Number of leukemic cells	Suspended in saline "Takes"/number of mice	Suspended in cobalt-cysteine solution "Takes"/number of mice
1,000,000	1/2	3/5
170,000	5/5	0/5
30,000	2/5	0/5
5,000	0/5	0/5

An observation by Duran-Reynals in fowl sarcomas may also prove of interest in this discussion. Duran-Reynals has pointed out that the virus of fibrosarcomas are detected more frequently at the age of 5 to 10 months than in younger or older fowls.

Whether or not these findings have any bearing on "transmission" of leukemia in mice cannot yet be decided. In our experiments, no attention was paid to the age of the donor animal or to that of the tumor tissue, nor was it possible to pay regard to such changes of character as might have taken place in the inbred mouse strains during the passages.

Attempts have further been made to repeat Gorer's experiments mentioned above. In our experiments, different tumors were inoculated into mice belonging to three different strains in which the tumors used did not take. Inoculation was made subcutaneously and repeated every two weeks (see table 2), one half of each litter being left untreated as controls. The three strains employed were the strain Aka, the strain dlb, and the strain Street. The strain Aka has a spontaneous leukemia incidence of 57 per cent, in the strain dlb (subline of the Little DbA), leukemia will develop in 1 per cent, and mammary carcinoma in about 40 per cent, and in the strain Street, leukemia incidence is 1 per cent, the incidence of mammary carcinoma

being 25 per cent. The transplanted tissues in question were a mammary carcinoma from dlb-mice, a leukemic tissue from Aka-mice, and a squamous cell carcinoma from the strain Aka which had been transferred through several passages (see Engelbreth-Holm 1944)

Further details of the experiment may be seen in table 2. The treatment did not increase or accelerate tumor development, and the results of Gorer's investigation were therefore not confirmed. Unfortunately, however, owing to a fulminating epidemic, all the animals died when 17-19 months old, and it is impossible to decide how many tumors might have developed if the mice had not succumbed prematurely. Nevertheless, since tumors occurring in these strains will generally develop spontaneously from the age of 10 to 12 months, the climax being at about 15 months, it was clear that the treatment did not accelerate tumor development, both the experimental and control animals presenting only a few tumors.

TABLE 2

Tumor tissue from	Inoculation made into	Number of inoculations	Age of mice at the end of experiment
Mammary carcinoma dlb	24 Aka-mice	3	17-19
	53 Street (24 ♂ 29 ♀)	5	
Leukemic tissue Aka	55 dlb	6	18
	(34 ♂ 21 ♀)		
	52 Street (30 ♂ 22 ♀)	6	18-19
Squamous cell carcinoma Aka	49 dlb	6	17-18
	(28 ♂ 21 ♀)		
	54 Street (30 ♂ 24 ♀)	6	17

The result in each instance was No effect upon tumor development

We have thus been unable, with the strains used in these experiments, to repeat Gorer's finding that inoculation of heterologous tumor tissue can bring about an increased leukemia incidence.

DISCUSSION

A series of experiments is reviewed, although largely supporting each other, they have proved inaccessible to direct reproduction. The various positive investigations originally indicated that development of spontaneous leukemia in inbred mouse strains is accelerated after the injection of embryonic extract or leukemic tissue extract, or after inoculation of heterologous tumor tissue.

MacDowell and his collaborators succeeded in accelerating the leukemia incidence after administration of embryonic tissue extract. Gorer did not succeed in reproducing these experiments, but he gives few details of his negative result to which, indeed, he seems to ascribe but a limited importance.

Englebreth-Holm and Frederiksen thought that they had accelerated the development of leukemia, or transmitted the disease, by means of an anaerobically prepared extract of leukemic tissue. These findings, however, have remained refractory to reproduction in spite of repeated attempts made by MacDowell and ourselves.

MacDowell observed acceleration of leukemia in one experiment by means of a cysteine-containing suspension, but neither he nor we have been able to repeat this observation.

After transplantation of a nontaking tumor tissue, Gorer achieved an accelerated development of leukemia. Despite several attempts to repeat these experiments, however, we have not succeeded in confirming Gorer's results.

How these discrepant findings are to be explained is still obscure. The various control series have been adequate, and no experimental faults which might have produced the positive or negative results have been detected. Most peculiar is the fact that the three positive series of experiments quoted, although mutually different, show one common feature, viz the injection of rapidly growing tissue or tissue extracts, that is, of homologous or heterologous tumor tissue, and of embryonic tissue extract.

It is a most fascinating thought that in these experiments we may be approaching a factor capable of accelerating tumor development, but undeniably, there must still be a number of factors escaping our control.

Transient changes of disease conditions in the mouse strains used can probably be excluded, to judge from the control series. Certain more recent experiments, however, may possibly throw light on these questions. Silber claims to have transmitted sarcomas in mice by means of cell-free filtrates, using the same technic as we did in our earliest experiments, but he points out that only filtrates from quite young tumors have any effect, and Duran-Reynals has shown that detection of virus in fowl sarcomas most easily will be successful in certain age groups, younger and older animals offering more difficulties.

It is premature to attempt to assess the importance of these experimental results to mouse leukemia, but they seem to call for a re-examination of the relevant problems on a wider basis.

IS LEUKEMIA A DISEASE OF THE RETICULO-ENDOTHELIAL SYSTEM?

By BRUCE K. WISMAN, M.D.

AT THE twenty-second year milestone following discovery of a rewarding treatment of pernicious anemia by Minot and Murphy, there is little doubt that the problem presented by leukemia is more important than any other in the field of hematology. Whether the increasing incidence in this disease is actual or only apparent due to more refinements in diagnosis (especially the widespread use of bone marrow biopsy) and more physicians interested in hematology is debatable. In any case, the frequency with which this diagnosis is made is undoubtedly rising.¹ This fact is highlighted by the observation that little or no real progress has been made in pathogenesis or treatment, since with unimportant exceptions, the efficiency of treatment by blood transfusions and x-ray therapy is still supreme (and unsatisfactory) and the prognosis for longevity remains unchanged. These facts suggest that a fresh, if not new, point of view with respect to this disease would not be undesirable. The present observations in a series of clinical and hematologic studies of monocytic leukemia may suggest an important role of the reticulo-endothelial system in the mechanism of the production of leukemia.

THE RETICULO-ENDOTHELIAL SYSTEM

Although ameboid cells in the connective tissues, distinct from the blood cells, were described as long ago as at least 1863,² it remained for Aschoff in 1913, working with vital staining methods using lithium carmine, to recognize that the phagocytic cells described by various cytologists under varying names were widespread throughout the body, forming a system of cells.³⁻⁴ Almost at the same time, hematologists were struggling with the problem of the identity of the monocyte, thought to be a white blood cell with exceedingly well developed powers of phagocytosis but resembling the neutrophilic leukocyte on the one hand and the lymphocyte on the other. These conflicting observations were resolved by Schilling-Torgan⁵ by establishing that the monocyte is a separate cell type. This was the general situation until 1925 when abundant evidence began to accumulate from the study of inflamed tissue and especially from tissue culture techniques⁶⁻¹⁰ that monocytes and clasmotocytes were capable of transformation from one to the other (table 1). Recently, in our laboratory, this transformation has been convincingly demonstrated by Houghton¹¹ with a single cell tissue culture technic. This observation has been further strengthened by the identification of transitional types of mononuclear phagocytic cells in human blood which, when strained supravitaly, have characteristics of both monocytes and clasmotocytes (see also fig. 6).

At present, therefore, it seems to some of us rather convincingly demonstrated that the monocyte is a derivative of the reticulo-endothelial system and that this system, having a blood as well as a tissue component, greatly exceeds in extent and

From the Department of Medicine, College of Medicine, Ohio State University, Columbus, Ohio

importance that which was originally indicated by the concept of Aschoff and Kiyono Monocytic leukemia, therefore, may be regarded as fundamentally and in fact as a leukemic reticulo-endotheliosis Monocytic leukemia might, therefore, furnish a valuable approach to the study of the various reactions and potentials of the reticulo-endothelial system of cells when under intense stimulation

REACTIONS OF THE RETICULO-ENDOTHELIAL SYSTEM TERMINATING
IN MONOCYTIC LEUKEMIA

During the past seventeen years in our clinic at Columbus, 192 cases of monocytic leukemia have been studied Many of these have shown the most unusual cytologic reactions in our entire experience with the blood dyscrasias of all types This has recently been the subject of comment ¹² ¹³ Cases initially appearing to be

myeloid, or lymphatic leukemia but terminating as classic monocytic leukemia have been seen in addition to those which showed approximately equal numbers of all three cell types throughout the entire course of the disease Instances in which there was an early stimulation of megaloblasts have been observed Polycythemia vera coexisted in one case In several instances, long remissions¹⁴ with near normal hematologic recovery occurred at a time when with marked anemia and thrombocytopenia existing the disease was thought to be far advanced Examples of a few of these unusual hematologic reactions will be given in brief summarization

CASE REPORTS

Case 1 (Fig 1) This patient, a colored male, age 28, was first seen on December 30, 1946, presenting marked generalized adenopathy and splenomegaly The lymph nodes were exceedingly hard upon

palpation and the spleen quite nodular but also very hard. Repeated bone marrow aspirations from the sternum failed to show many free cells, the bone marrow content being chiefly reticulum cells and a few monoblasts. Bits of solid bone marrow tissue, however, consisted almost entirely of reticulum cells. An occasional megakaryocyte was seen and a fair sprinkling of myeloid cells in all stages of maturation. Lymph node biopsy showed complete loss of architecture, the cellular content being composed almost

Fig. 1. Graph of the hematologic reactions in a patient with "pure" reticulo-endotheliosis. Case 1 of text. White cells in semi-logarithmic scale.

entirely of reticulum cells and monoblasts. Reference to figure 2 shows increasing difficulty in the supply of circulating blood elements, even before the application of the nitrogen mustard and deep x-ray therapy, which, incidentally, resulted in no visible decrease in the size of the adenopathy or splenomegaly.

This case is shown as an instance of reticulo-endothelial hyperplasia with very little tendency to do other than reduplicate its own type of cell. This, therefore,

would be an instance of almost "pure" reticulo-endotheliosis, and is to be contrasted especially with the following case

FIG 2. Graphic representation of the blood findings in a patient with aleukemic reticulo-endotheliosis. Case 2 of text. The differential cell-count of the bone marrow as obtained by the aspiration technique is shown in the vertical panel on the right. Nucleated red cells listed refer to the number encountered in counting 100 white blood cells.

Case 2 (Fig 2). This patient, a white male aged 84 years, has been ill for sixteen months, during which time his clinical and hematologic state has varied little. He has received blood transfusions about once a month to maintain his red cell count. There is no apparent physical deterioration and he goes about in the same fashion as almost any man of the stated age. Figure 2 shows the hematologic record

for a typical month (March, 1947), during which time he received urethane. Although this medication apparently improved the levels of blood platelets and neutrophils, it was discontinued because the patient definitely felt worse when he was on this form of treatment. Of importance to the present discussion is the fact, clearly shown on this graph, that the level of monocytes in the blood are very low with no immature forms present at all, while the bone marrow constantly shows a small, but definite, percentage of monoblasts which does not vary appreciably from time to time.

FIG 3 Graphic representation of the blood findings in a patient in which transition from aleukemic to leukemic monocytic leukemia occurred. White cells in semi-logarithmic scale. Case 3 of text. The differential cell-count of the bone marrow in the aleukemic phase is shown in the vertical panel on the right. Nucleated red cells listed refer to the number seen in counting 50 white blood cells.

This case illustrates a minimal reaction of the reticulo-endothelial system in the direction of producing monoblasts with little tendency for maturation to monocytes. This is reflected in a clinical course that is unchanging, paralleling the stationary character of the hematologic reaction.

Case 3 (Fig 3) This patient, a white female, aged 46 years, illustrates the transition from an aleukemic state, in which no qualitative or quantitative changes in the blood monocytes could be detected, to a frank monocytic leukemia. Also illustrated is the deceptiveness of attempting to interpret the bone marrow findings as obtained by the aspiration technic when the marrow does not aspirate freely. Re-

peated samplings of the marrow were attempted from the sternum but only a few drops of acellular fluid were obtained on each occasion. In this material no free monoblasts and no increase in monocytes were obtained, as shown in figure 3 (right panel). Monoblasts first appeared in the blood seven days before death, but monocytes were never increased.

Case 4 (Fig. 4) Demonstrated here is a case of monoblastic leukemia in which, during the early phases of the disease, an appreciable number of megaloblasts were found in the bone marrow, when monoblasts were not apparent in this tissue. When leukemia first became clearly evident, small numbers of monoblasts began to appear in the marrow but megaloblasts were no longer to be found. Later, large numbers of monoblasts were present in both blood and bone marrow.

FIG. 4 Hematologic graph of a patient with monocytic leukemia in which megaloblasts and increased numbers of early erythroblasts occurred in the bone marrow during the early course of the disease. Case 4 of text. Typical bone marrow findings are given during the early phases (first vertical panel on right of graph) and late phases (second vertical panel) of the leukemia. Nucleated red cells shown indicate number seen in counting 100 white blood cells. White cells plotted in semi-logarithmic scale.

The data in this case suggest a low grade stimulation of the reticulo-endothelial system, in the early phases of which pathologic megaloblasts were the first abnormal free cells to appear in proximity to reticulo-endothelial tissue, later, the stimulus resulted in more directional changes in terms of formation of monoblasts.

Case 5 (Fig. 5) This case of monocytic leukemia is remarkable because of the coincident polycythemic levels of red blood cells. The patient had a large spleen (extending to the level of the umbilicus) which was removed at another hospital, the tissues being unfortunately lost. When first seen in this clinic the usual clinical signs of polycythemia vera were present, i.e., cherry red mucous membranes, liver-like tongue, distended dark retinal veins, chronic conjunctivitis, etc. There was no adenopathy.

The initial blood examination (fig 5) showed high levels for all the circulating blood elements including reticulocytes. However, the only pathologic white cells found were monoblasts although young and mature monocytes were distinctly plentiful. Radiation therapy with radioactive phosphorus as shown

Fig 5 Hematologic graph in a patient with monoblastic reaction occurring coincidentally with the blood and clinical findings of polycythemia vera. Case 5 of text. Bone marrow count is shown in the vertical panel on the right. Nucleated red cell elements are given as the number encountered in counting 100 white blood cells. White cells in semi-logarithmic scale.

presumably has decreased the monoblasts in the blood almost to the vanishing point so that now the patient shows little else than the classic hematologic and clinical signs of polycythemia vera.

We interpret these bizarre hematologic events to be the result of increased stimulatory effects upon the reticulo-endothelial system with dominate effect upon the

intersinusoidal reticulo-endothelial system capillaries (red cell-forming precursory tissues) of the marrow, producing increased numbers of mature erythrocytes. Elsewhere, this stimulus results in a monocytic response resembling the average

FIG. 6 Graphic representation of the blood findings in a case of myeloblastic leukemia, later terminating as monoblastic leukemia. Case 6 of text. White cells in semi-logarithmic scale.

case of monocytic leukemia except for the unusually favorable response to radiation therapy.

Case 6 (Fig. 6) This patient initially presented with the peripheral blood and bone marrow findings of myeloblastic leukemia. As shown in figure 6, neutrophilic leukocytes constituted 80 per cent of the circulating level of 50,000 white blood cells, indicating that our diagnosis of the immature cells present

at that time as myeloblasts and not monoblasts was probably correct. Subsequently, and coincidentally, with radiation therapy as shown, the myeloid reaction completely disappeared to be replaced by a blood and bone marrow picture of monocytic leukemia which persisted until death. Autopsy findings in this and the preceding cases were those usually noted in monocytic leukemia described in a previous publication from this¹⁵ and other laboratories.¹⁶ There is some evidence here that myeloblastic leukemia may

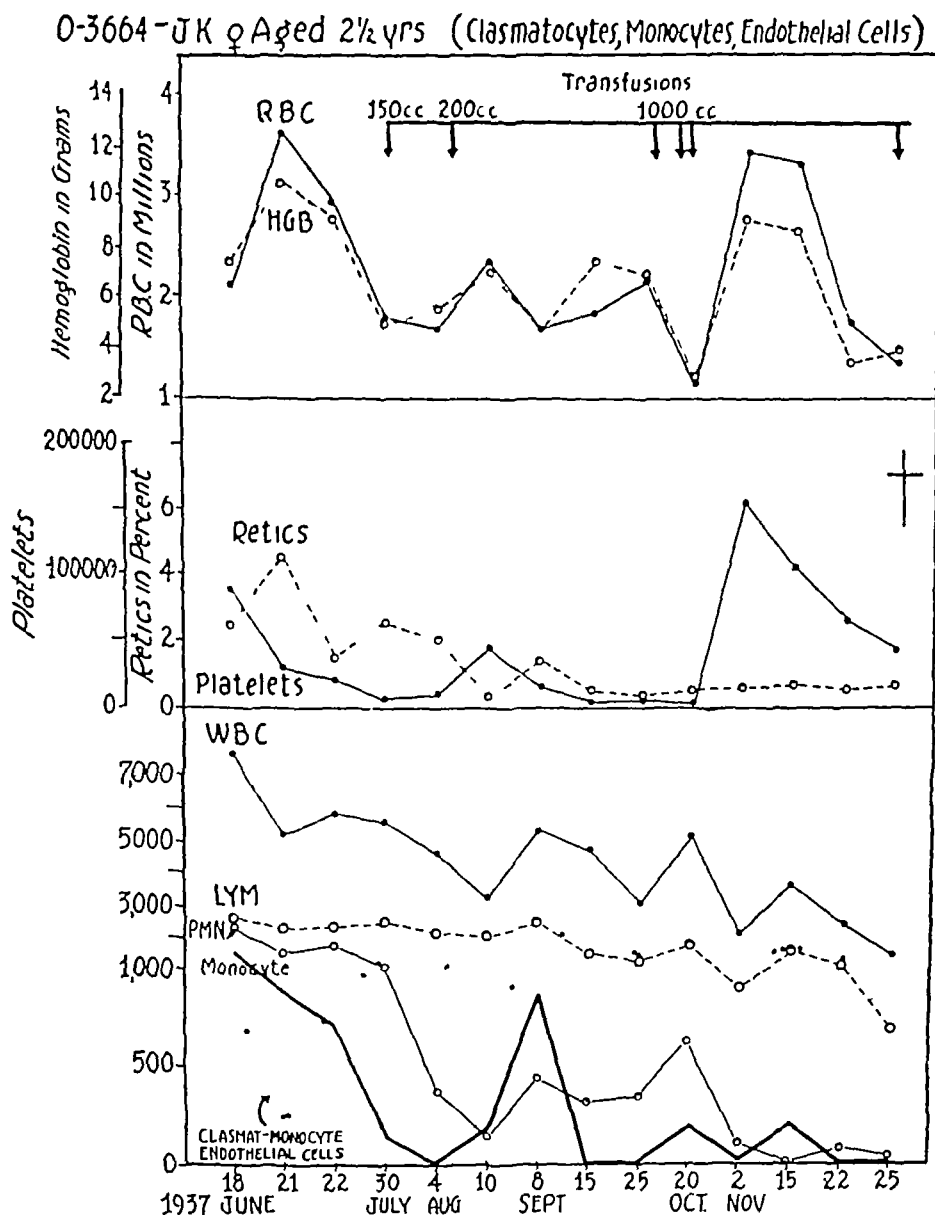

FIG 7 Clasmatocytic leukemia characterized by many transitional phagocytic mononuclear cells. Hematologic graph of a case of reticulo-endothelial leukemia. Case 7 of text. White cells in semi-logarithmic scale.

be one manifestation of reticulo-endothelial disease. If the myeloblasts did not arise originally from reticulo-endothelial stimulation, it is difficult to understand why the proliferation of these cells did not persist with the advent of the monocytic reaction.

Cases similar to the above, in which the initial cell stimulation consisted of lymphocytes with immature lymphoid elements present, and others in which im-

mature elements of all three types of white blood cells were increased in approximate equal proportions, have been previously described and reported from this laboratory¹⁵ and need not receive additional emphasis in this communication

Case 7 (Fig 7) This patient furnishes, through the observed hematologic reactions during her illness, additional evidence that the reticulo-endothelial system may undoubtedly undergo stimulatory changes resulting in a leukemia of reticulo-endothelial cells. In this chart, only morphologically classic monocytes are labeled as such, represented by the heavy solid line. However, the dotted line of the graph represents phagocytic cells, many of which had predominating monocytic characteristics as well as cells that were definitely clasmatocytes and endothelial cells. There is little doubt that this was a leukemia of reticulo-endothelial elements in which monocytes participated as one of the pathologic cells. Blood cultures were sterile and there was no evidence of bacterial endocarditis or other sepsis.

DISCUSSION

Doubt that monocytes are derivatives of the reticulo-endothelial system, and that monocytic leukemia is therefore not a disease of this system of cells has often been expressed,¹⁷ chiefly because reticulo-endothelial hyperplasia is not always demonstrable in this disease. It should be pointed out, however, that numerical increase in the reticulum and specific endothelial cells probably will not be apparent unless maturation of these elements is obstructed. That is to say, when cell division *and* maturation occur uninhibited, hyperplasia of that cell type often is not apparent by microscopic examination of the tissue in question, the numerical increase is noted only in the end-state cell. An excellent example of a tissue reaction supporting this statement is furnished by almost universally accepted observations in pernicious anemia. During the phase of relapse, megaloblastic hyperplasia with the separate power of division of the cell intact is outstanding in the near absence of maturative principle. When the maturative principle is supplied, however, megaloblasts rapidly disappear, so that within forty eight hours and thereafter, no greater number of megaloblasts can be found in the bone marrow than is apparent in a normal resting marrow. Within seven days, however, mature red blood cells are being supplied to the circulation in maximum numbers, i.e., only the end cell product is visibly increased, although little doubt can be entertained that these new red cells are taking origin primarily from the megaloblasts. There is little reason therefore to demand visible evidence of reticulo-endothelial hyperplasia in monocytic leukemia to satisfy the hypothesis that in this disease the monocytes take origin from the reticulo-endothelial system. *In a blood cell strain, it is only the cell in the end-stage of maturation that regularly shows appreciable and visible quantitative increase under conditions of stimulation, not the precursor cells.*

If this statement is accepted, it follows that there is no valid reason to discount the distinct possibility that leukemias of all cell types are primarily diseases of the reticulo-endothelial system. The case studies cited in the foregoing part of this paper offer some evidence that under an unknown type of stimulus to the reticulo-endothelial system (as indicated by the advent of monocytic leukemia at some phase of the disease), there may be formed large numbers of myeloblasts, lymphoblasts and even megaloblasts. It is possible in the cited cases that hyperplasia of one or another of the types of cells occurred because maturative substance for that

cell type was temporarily deficient. Eventually, the body resources were able to mobilize adequate quantities of maturing substances for this cell type, the final failure coming in inability to supply sufficient cell maturing factor for monocytes, thus in the end determining the death of the individual from monocytic leukemia.

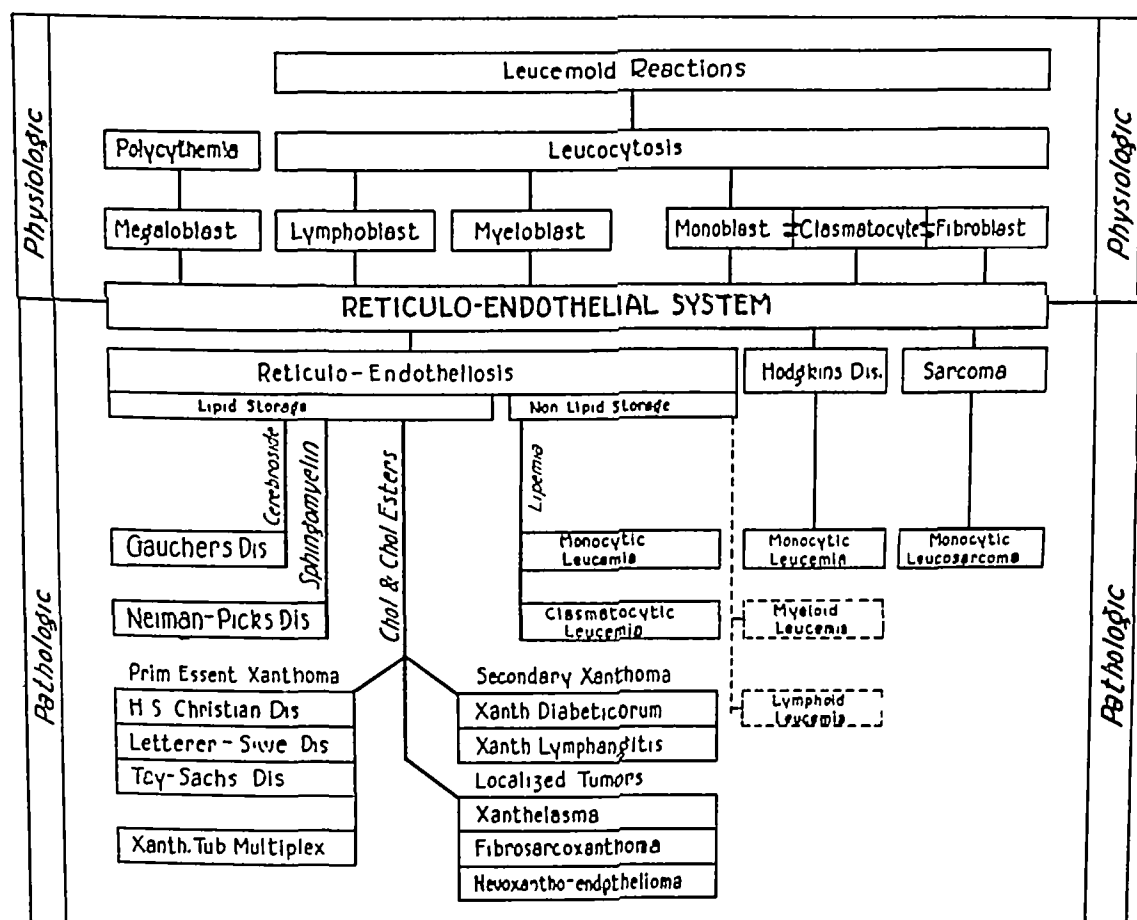

FIG 8 Diagrammatic representation of the relationship between the reticulo-endothelial system, normal blood formation (upper one-third of chart) and pathologic reactions producing disease (lower two-thirds of chart). This chart expresses the view that neoplasm of the reticulo-endothelial cells (labeled sarcoma) gives a different reaction than that of the bulk of the diseases of the reticulo-endothelial system (labeled reticulo-endotheliosis), the latter being characterized by, among other things, disturbances in lipid metabolism. Hodgkin's disease is shown as a third form of disturbance of reticulo-endothelial tissue. It is possible that sarcoidosis (not shown) is a fourth variety of reticulo-endothelial disease. Myeloid and lymphoid leukemia are indicated in broken lines as possibly also a primary disease of reticulo-endothelial cells as suggested in text.

This discussion leads to the following suggestions of a possible mechanism for the production of leukemia:

1. Leukemia, irrespective of cell type, may be the result of unknown stimulatory effects upon the reticulo-endothelial system.

2. The type of leukemia observed may be determined by the failure of the body to supply specific maturative substance or substances at one or more phases in development in that cell strain in quantity to keep up with the particular intensity

of reticulo-endothelial stimulation operating at that time in that individual organism

3 Specific cytologic maturative substances may be multiple in types and chemical identity and failure of supply of one type may not necessarily prejudice adequate supplies of another type "The chain breaks at its weakest link"

4 The bizarre varieties of leukemia regularly seen in all hematologic laboratories may result from multiple mixed failures of maturation factor varying as to type specificity and as to degree

This explanation of the production of leukemia, although admittedly speculative, satisfactorily accounts for many if not all of the puzzling features regularly encountered in patients with this disease by using only one basic mechanism without recourse to multiple theories. The concept of specific cell maturation substances is cytologically correct and the existence of one such substance for megaloblasts has been proved. In addition to the need for more information relating to other maturative factors, more facts are needed with respect to influences that are stimulatory to the reticulo-endothelial system. Particularly, in this regard is there need for additional study of lipid metabolism and the influence of lipids upon this system of cells¹⁵⁻¹⁸⁻²⁰ (fig. 8)

SUMMARY

1 Evidence is given from case study of reticulo-endothelial disease supporting the concept that monocytic leukemia is one form of reticulo-endotheliosis

2 On the basis of varied types of cell reactions seen in monocytic leukemia, it is suggested that all forms of leukemia may be hematologic varieties of reticulo-endotheliosis

THE POSSIBILITY OF PRECIPITATING THE LEUKEMIC STATE BY EMOTIONAL FACTORS

By F R MILLER, M D , AND H W JONES, M D

LEUKEMIA in the human individual may develop without any known precursor, but frequently it occurs following a precipitating incident or set of incidents. It is apparent from a review of the literature that various physical, chemical and possibly infectious agents are involved in the inception of some of these diseases.¹ Exposure to irradiation from x-ray or radium, contact with or exposure to benzol or its derivatives, physical trauma, and the use of arsenical and sulphonamide drugs are some of such agents. Infections which seem to have played a part in precipitating these diseases are tuberculosis, syphilis and pneumonia. The relation of infection in this regard is not as well established as that of the physical and chemical agents. Exposure to benzol and exposure to irradiation from x-ray or radium are more clearly related to the precipitation of the leukemic state than is exposure to other agents.

No one believes that these agents cause leukemia, but it is possible that each may act to upset the normal balance of blood formation so that leukemia results.

Results of experimental work^{2 3 4} point to the normal control of blood formation by hormonal as well as dietary factors. If leukemia is precipitated by these chemical and physical agents, this probably is brought about by changing the hormonal balance. In those cases of leukemia in which such agents are not uncovered in the pre-leukemic history, it is possible that emotional factors may have acted in a similar role in precipitating the leukemic state.

For many years, the influence of emotional reactions on physiologic processes has been well known, but only within comparatively recent times have studies revealed the significance of emotional factors in precipitating or aggravating a number of disease processes such as peptic ulcer, asthma, mucous colitis, etc. As the etiologic importance of these factors has been demonstrated, a much better understanding of these illnesses has been brought about. Milkorath⁵ and his co-workers showed that leukocytosis, with a normal differential, "appeared to be intimately related to the psychopathologic emotion." They explained the elevation of the total white cell count on the basis of a "redistribution of the white cells from the organ reservoirs." It is well known that there is an intimate interrelationship between emotional factors, the autonomic nervous system and the endocrine glands. These findings, therefore, have led us to believe that the frequent occurrence of emotional difficulties in patients with leukemia may be more than a coincidental finding. Often these patients volunteered a great deal of material concerning their own psychologic difficulties. Therefore, we have endeavored in a few cases of leukemia to determine the emotional background, and in this paper we wish to present and discuss the emotional histories of 6 cases prior to the development of leukemia.

From the Charlotte Drake Cardeza Foundation, Jefferson Medical College Hospital, Philadelphia, Pennsylvania.

brought up on a farm but at the age of 21 he was restless and ambitious to go into business. He married at 20 and his wife was never well. At 22, he worried over financial losses incurred in a filling station which he owned. His wife died, four years after their marriage, while giving birth to a child. He was worried and grief-stricken but he worked hard and did fairly well in business, saving about \$20,000 up to 1929. From 1930 through 1933 he was worried about finances most of the time. He lost his business, spent his entire savings and then went back to work for his father on a fruit farm. There he made no money, was depressed and later fought with his father and left the farm discouraged and unhappy. Throughout this entire time, he was physically well. In 1934, he again tried to go into business, determined to make good, and throughout 1934-7 he was not so easily worried and his finances were a little better managed. In 1937, he had his teeth extracted and he bled considerably and this again worried him. He also tired easily at this time and had no pep. In 1938, he used up his savings again, was unable to work well and everything then seemed to go from bad to worse. He was afraid, and seemed to have lost his nerve, and he cried easily. Late in 1938, the diagnosis of chronic myeloid leukemia was made. This patient died at home, May 1940. A necropsy was not obtained.

Case 4 G. P. was a 46 year old man who was first seen in the Jefferson Hospital, Philadelphia, clinic the winter of 1940. He had had chronic myeloid leukemia for six years, and had been treated in several other clinics. A psychiatric interview was held in October 1940. He was of German-American extraction. His school work had been of good quality but he went to work immediately following graduation from high school. At about 25 years of age he went to work for a rubber company and a year later was married, but almost immediately afterwards he was transferred from New Jersey to a plant in Canada. Here he was placed in complete charge of construction, production and sales of a new branch of his company. His wife, however, remained in the United States the first year. Almost the entire burden of responsibility of the new plant was carried by him. He had few friends and almost no one to whom he could confide his difficulties. He was under considerable tension and felt that the responsibility was very great. At this time he began to have queer sensations in his stomach and his digestion was poor. He became easily fatigued and had great difficulty in sleeping. A little later he began to have attacks of vomiting and severe headaches. These symptoms lasted for several years and were pronounced whenever the pressure of business was heaviest.

His first child was born when he was 34. At the age of 37, or two years before leukemia was apparent, his branch of the company lost \$70,000 during the year. This was an added source of anxiety to him and he took the responsibility for the loss. His second child was born four months before the diagnosis of leukemia was made. At this time, he was overworked and worried because of the company finances as well as his own. He developed an infection of his neck and during the care of this, leukemia was discovered.

Anxiety and worry concerning his family and company were not lessened with the diagnosis of leukemia but he became philosophic. He said that he believed there were spontaneous remissions and that he would have one. He read much concerning leukemia and he tried to help in caring for himself.

He stated that he had had definite mood swings all his life, some weeks he felt on top of the world, other weeks he was down in the dumps and every little job looked twice as big as it ought to. His leukemia was discovered in December 1933 and continued through March 1941, or over seven years. He died in Memorial Hospital, New York City, March 1941, and a necropsy revealed typical findings of chronic myeloid leukemia.

Case 5 P. H. was a 53 year old white man. He entered Lakeside Hospital, Cleveland, in the winter of 1939 where a diagnosis of chronic myeloid leukemia was made. In February 1939, a psychiatric interview was obtained. The patient had worried over small things his entire life. In 1918 he worried himself sick about everything. He had been a caretaker on an estate and he had worried about his duties, he did not believe he was doing well and everything seemed to go wrong. He became depressed and could not sleep and he lost his appetite. The estate was then sold and he became caretaker on another. The owner committed suicide, but before this happened he had felt better and was doing rather well. The suicide was a shock to him. Following this episode he had worked on yet another estate for a period of eight years. While working on this estate, he was worried and sensitive to criticism. During this time, his father died and he became depressed. He worked night and day but seemed to be in a rut. He again changed his position and became even more worried. At this time he believed someone was poisoning the

pheasants he was raising and thought that this was being done to change the control of the estate. This led to a fight with another man on the estate.

In August 1938, he became extremely depressed and wanted to die. He thought people were making fun of him and believed that someone had it in for him and was plotting against him. He thought that "the world was wrong." Then he lost interest in everything and could neither eat nor sleep. He lost his self confidence, and was always afraid he would make mistakes. Although he had death wishes, he had no suicidal ideas. He cried a great deal, and he tried to be alone and would walk the streets. His depression grew worse until, in November 1938, he was physically sick. At this time he had pains in both hips and numbness and tingling from knees to feet. He had no vitality or energy and felt a pressure on top of his head and pain in the back of his neck. He thought he was going to die and made a will and just waited. In February 1939, it was found that his spleen was enlarged and that his leukocyte count was elevated. The patient died in Lakeside Hospital, August 1941. The necropsy findings were typical of chronic myeloid leukemia.

Case 6 M. A., a 40 year old white woman, entered Jefferson Hospital, Philadelphia, in December 1946. A psychiatric interview was held in January 1947. The patient appeared pale, underweight and considerably older than the age of 40. She wept when she talked about her husband. She is married to a miner and has nine children. Her husband is an alcoholic who has been cruel and a poor provider. After twenty years of marital difficulty, she finally forced her husband to leave their home in October 1945. At present she has \$93 a month from Mother's Relief and a few dollars irregularly from her husband to care for her nine children.

She was one of four children. Her father was an alcoholic and he was unstable. She stopped school at the age of 14—the 6th grade—because she had to work and help support the family. Despite her difficult life there were few somatic complaints until two years ago when she began to be easily fatigued and lost weight. It was at this time that the difficulty with her husband became acute.

She is a Catholic and very religious. The impression of the interviewer was life-long insecurity related to difficult environment and a lack of affection as a child. Her main defense was compliance, religion, patience and acceptance. It is difficult to evaluate the exact relationship between her emotional difficulties and her present disease, but it is apparent that the emotional difficulties have played a part in the development of the organic disease.

It was found in October 1946 that her spleen was enlarged and the leukocyte count was elevated. She is now being given treatment for chronic myeloid leukemia.

DISCUSSION

In this short series, only cases of chronic myeloid leukemia have been included. Psychiatric interviews, however, have been held with 3 patients with chronic lymphoid leukemia and only one of these has given much evidence of emotional difficulties in the background. One patient with chronic eosinophilic leukemia was also interviewed, and it was found that following an accident in the plant in which he worked he frequently had somatic symptoms when he was in the room in which the accident had occurred. Otherwise, there was little in his pre-leukemic history which might have acted to precipitate the disease.

Psychiatric interviews have not been held with patients with acute leukemia, nor have we examined the emotional background of either patients or parents of any of the childhood leukemias.

Clinical data of all types have been left out of this report because each case represented a typical picture of chronic myeloid leukemia. In only one of these patients, Case 4, was there any evidence in the pre-leukemic history of chemical or physical agents which might have precipitated the leukemia. This man worked in a rubber plant but he was not exposed to chemical agents.

Anxiety, depression and chronic worry affected 4 of the 6 patients of whom

case reports are given. Each of these 4 had conversion symptoms such as nausea, vomiting and loss of appetite. One had pain in his hips and a feeling of pressure at the top of his head. Three of these 4 had loss of appetite and sleeplessness. Three of these 4 cried easily so that it might be said that each of the 4 was somewhat emotionally unstable prior to the development of leukemia. One of the other 2 had had emotional strain as a girl and later hysteria, difficulties and disappointments because she married a man she did not wholly love. The sixth had led a life of misery as a child and for twenty married years. It may not be entirely convincing that the material in such histories has precipitated the leukemic state. Heuper¹ has stated that the leukemic state has not been precipitated by emotional or psychic trauma. These histories, however, run somewhat contra to this statement.

Recently, it has been shown that in the past forty-five years there has been a marked increase in the incidence of leukemia.⁵ Drugs, industrial hazards, irradiation from x-ray and atomic sources, and the increased hazard of physical trauma of our age may have brought about this increase. The increased tempo of life in the past forty-five years, with its increased sources of anxiety, worry and emotional stress and strain, may also have aided in increasing the number of deaths from leukemia.

It seems to us that all cases of leukemia in adults should be studied for any and all factors which may have played a part in the precipitation of the disease and such a study should include emotional factors. Against a statistical study of emotional factors in all cases, there should be plotted a particular study of those cases in which other factors have been ruled out.

SUMMARY

The emotional background of 6 cases of chronic myeloid leukemia are reviewed after psychiatric interviews. In 4, emotional instability was of long standing and in these 4, chronic worry and anxiety seemed to be an integral part of the pre-leukemic history. One of the other 2 suffered emotional trauma early in life and one had lived a life of misery as a child and an adult. Further study of emotional factors in relation to pre-leukemic histories should be made.

THE PRESENT POSITION IN THE TREATMENT OF CHRONIC MYELOID LEUKEMIA

By A. PINNEY, M.D., M.R.C.P.

IT IS not proposed to devote this article to a detailed description of the various methods of treating chronic myeloid leukemia or to a statistical assessment of the results. The aim is rather to consider the theoretic bases on which the different forms of therapy have been devised, while, incidentally, indicating whether the observed results are such as to support the hypotheses.

That the problem of the etiology of the leukemias is almost as obscure as it was a century ago, when Hughes Bennett and Virchow, independently of one another, published the first accounts of the disease, is indisputable. And this assertion is not invalidated by the discovery of the transmissible leukemias of lower animals, which has, in fact, complicated, rather than clarified, the problem of the disease as it is observed in man. But in spite of the distressing lacuna in our knowledge, research into the treatment of the chronic forms of leukemia has been pursued in a manner, which has, on the whole, been scientific, rather than purely empiric. And this has been possible because we are less abysmally ignorant of the underlying pathologic and cytogenetic factors than we are of the causative ones.

For instance, it is patent that, in the leukemias, there is gross overgrowth of hemopoietic tissue, which in the case of our present subject of discussion—chronic myeloid leukemia—is the bone marrow. And, at this point, it is important to realize that the intense proliferation of white cells in the marrow is not to be considered as an example of hyperplasia, because that concept includes that of increase in the number of normal cells in normal arrangement, with, as a result, increased, but essentially normal, functional ability. Thus, the extremely active cellular marrow found in many infections is an example of hyperplasia, whereas the more or less disorderly proliferation in myeloid leukemia is to be considered as pathologic overgrowth. And this is true whether the malady be included with the neoplastic ones or not.

Now, in normal postnatal life, the mature granulocytes found in the circulation arise from mitotic division of granular myelocytes. That is to say, the polymorphonuclear leukocytes, with their specific granulation, arise from simpler cells, which do, however, already possess characteristic granules in their cytoplasm. Less mature cells—myeloblasts—are not involved in the process, forming, as it were, a reserve of stem-cells which are not normally called into action, and, even in severe infections, the marrow contains few myeloblasts, whereas myelocytes are very numerous and show signs of active proliferation. In fact, it is probably true that extension of the genealogic tree back to the myeloblast stage results in the formation of abnormal granulocytes. In other words, there is reason to suppose that the abnormal white-cells which are so prominent a feature of the blood and marrow in chronic myeloid leukemia are produced from maturation of myelo-

blasts, and this view is consistent with the generally accepted statement that the outlook is the worse the greater the proportion of myeloblasts in the marrow.

Deterioration, that is to say, a tendency towards acuteness, in chronic myeloid leukemia is detectable in the marrow earlier than in the blood, because there is great overgrowth of myeloblasts (at the expense of myelocytes) *before* there is any noteworthy change from the "chronic" type of blood picture. It is, therefore, reasonable to assume that conversion of chronic into acute leukemia comes about by a peculiar process of dedifferentiation.

First, there is increase in the number of myeloblasts in the marrow, although some or many of these cells have the power of maturing into more or less normal myelocytes, which, in turn, may give rise to polymorphonuclears or they may themselves emerge into the circulation. Secondly, there is still further deterioration of the functional activity of the myeloblasts, which lose their power of becoming differentiated into myelocytes, and this represents the stage of complete and irreversible conversion of chronic myeloid leukemia into the acute form. Of course, intermediate phases are well known, as witness the presence of ill-formed myelocytes in the peripheral blood.

The brief discussion above will serve as a preface to the more distinctly therapeutic problems which confront us, while, later, a rather more recondite consideration of the cytologic factors will be required as an introduction to the most modern methods of treatment.

Probably the oldest method of treating chronic myeloid leukemia is by administration of arsenic, and this is especially interesting as an example of more or less successful empiricism, because the mode of action of the drug in blood dyscrasias is still obscure. Now, of two facts, there can be no dispute: first, arsenic, properly exhibited, can bring about clinical and hematologic remission in many cases, and, secondly, that this is brought about by decreasing the activity of myeloblasts in reproducing themselves and in giving rise to myelocytes. In other words, arsenic, at least for a time, is able to cause leukocytopoiesis to proceed along more or less normal lines, while, at the same time, decreasing the gross overactivity of myelocytes in dividing and in differentiating into polymorphonuclears.

Physicians of a past generation, who, like us, were not averse to hiding ignorance under a cloak of words, valued arsenic for what was known as its "alterative" action. And it is indisputable that this term is admirably descriptive of the effect of arsenic in chronic myeloid leukemia. This was equally well shown, before the introduction of liver treatment, in pernicious anemia, by the effects on the erythrocyte picture.

There are many points of practical importance in connection with arsenical medication, as Forkner and Scott emphasized in 1931, when the drug, which had almost fallen into disuse in the treatment of leukemia, was given a new lease of usefulness.

A few of the advantages may be mentioned here. Thus, arsenic is cheap and easily available, and, if given in the early stages of chronic myeloid leukemia, it usually produces a good remission, which can sometimes be maintained for months or even years by continuing to administer maintenance doses. This second feature is a great

advantage over irradiation, which has, of course, to be interrupted when the blood picture is more or less normal, as, otherwise, aplasia of the marrow may ensue

Not only does arsenic cause a reversion of the leukocyte picture to a more normal composition, but it produces amelioration of the anemia. But it is debatable whether this is the result of a direct action of erythropoiesis, whether it is due to relief of pressure on the red stem-cells, or whether both (and perhaps other factors also) play a part

This is not the place to describe the minutiae of therapeutics, but it is well to point out that, when arsenic will no longer maintain the patient in a state of remission, irradiation may still do so. However, it is essential to recollect that exposure to therapeutic irradiation shortly after a prolonged course of arsenic is likely to cause more severe reactions than would a similar dose of x-rays in a patient who has not had the drug. This is alleged to be due to secondary radiation from the arsenic stored in the tissues, but whatever the explanation, a history of having taken arsenic for months before starting radiation treatment indicates the need for small and experimental dosage of x-rays

Conversely, arsenic may be effective in some cases which have become resistant to x-rays, still inducing a remission when irradiation will no longer do so. This is, of course, true only when the blood and marrow are still characteristic of the chronic form of the disease, but, if the failure of x-rays is due to conversion into the acute (myeloblastic) state, no known treatment will bring about a remission

Another method of medicinal treatment, which, like arsenic, has to some extent fallen into undeserved disuse, is benzol, which also has the advantage of being given by mouth, while the dangers which have been attributed to its administration are entirely the result of gross overdosage

Benzol is a well-known marrow poison, which has caused a good deal of trouble in various industrial processes for this reason. It appears to damage the platelets, the granulocytes and the red corpuscles in that order, affecting the parent-cells and so reducing the mature forms in the blood

It was this knowledge of the action of benzol which led to its use in treating leukemia, but there is no doubt that its effects are not entirely due to its myelotoxic action. If given in suitable doses, the leukocyte count falls as a result of decrease in the number of immature and abnormal white-cells, while the red count rises, and the changes in the marrow are of the same type, viz., decrease of myeloblasts and a more normal activity of the myelocytes. In fact, a new investigation of benzol is overdue, because it has now been established that prolonged exposure of healthy persons to small doses of benzol greatly increases the likelihood of the development of chronic myeloid leukemia

If benzol is given when the leukocyte count is very high, it is best exhibited in capsules with olive oil, each containing 0.5 Gm. of benzol. The course is started with four capsules daily, and, if there is no nausea, is rapidly increased to a maximum of eight or ten daily. This dose is continued until the leukocytes have fallen to about 50,000 per cu. mm., when the dose is gradually reduced until the white-cell count is about 15,000 per cu. mm. Then, it is often possible to find a suitable maintenance dose, usually in the region of 0.5 Gm. two or three times a week

Again like arsenic, benzol is still effective when radiation has become ineffective, but, unlike arsenic, a preliminary course of benzol is not liable to cause trouble during subsequent radiation treatment.

Benzol acts as an essentially destructive agent, which has a rather more powerful effect on immature cells than on mature ones; hence, the beneficial results in chronic myeloid leukemia. Unlike radioactivity and urethane, its effect on dividing cells is no greater than on resting ones, so that it cannot be regarded as affecting the essential abnormality which is the cytologic basis of the disease.

For many years, the usual method of treating chronic myeloid leukemia has been with x-rays, and, as the results obtained are rapid and spectacular, arsenic and benzol have fallen into a poor second place. As already indicated, the dislike of these two drugs is an ill-founded one.

Deep x-ray therapy can rapidly bring about a remission in the great majority of cases of chronic myeloid leukemia, but that is no reason for assuming that the radiologist is the right person to have charge in such cases. The disease lies in the province of the physician, who is in a much better position than is the specialist radiologist to determine the most suitable therapy and to assess the results in individual cases.

This is not a denial of the right of the radiologist to determine which particular technic of irradiation is to be employed, but, despite quite acrimonious divergences of opinion between different schools, it can truthfully be said that the results obtained by the different methods are all approximately the same. The length of the remission which is brought about is no longer when one radiologic technic, rather than another, is employed, and the development of radioresistance is not accelerated or postponed by any particular dosage or by exposures of different areas.

It is probably no exaggeration to say that the development of therapeutic irradiation in cases of chronic myeloid leukemia has never been exploited as fully as it might have been. Most physicians have been satisfied with the remission brought about by x-ray treatment and have kept careful watch for the earliest hematologic signs of relapse, and, when these have appeared, have returned the patient to the radiologist for further treatment.

The mild contempt with which arsenic has been regarded, and the fear of benzol as a possible cause of aplastic anemia, have prevented combined treatment from being used as extensively as might have been expected from our empiric knowledge of therapeutics. In part, of course, this failure has been due to the habit of handing cases of chronic myeloid leukemia to the radiologist.

That the length of a remission which has been induced by x-rays can be prolonged by administration of maintenance doses of arsenic or benzol is indisputable, but there are no published records of individual cases which have been dealt with in this way. More and more attention has been given to irradiation, and less and less to medicinal treatment. Thus, sodium phosphate, made radioactive by the cyclotron, has been hailed as a great advance in treatment, whereas, in fact, its main advantage is that it can be administered orally, while the results have been

much the same as those of other methods of exposing the leukemic cells to the destructive action of rays

Even the most enthusiastic advocate of radiation treatment has not, it may be assumed, ever supposed that the method, however modified it might be in the future, would result in cure of leukemia. Some workers have sought for a hypothetical virus, others for a toxin, and yet others for indications of a chemical or an endocrine factor, and it is probably correct to say that more and more adherents to the chemical (or constitutional) theory are won annually, although, of course, acceptance of this view does not exclude leukemia from the neoplastic class.

Only a very few indications of the evidence can be given here, but they may suffice to stimulate further work, while they form a more or less rational basis for the further discussion of medicinal treatment. First, there is the well-known fact that the incidence of leukemia may be familial, although, admittedly, this is far from common. Nevertheless, in the case of a disease so relatively rare, the existence of such cases suggests that some intrinsic factor is of etiologic importance, and such a view is supported by the distinctly greater frequency of the chronic myeloid form in Jews. Secondly, the fact that long-continued exposure to small concentrations of benzol (and perhaps of x-rays) increases the incidence of chronic myeloid leukemia seems to demonstrate that a chemical change underlies the abnormal proliferation which characterizes the disease.

But perhaps the best evidence, indirect though it is, may be found in certain more academic observations. Thus, the cytologic changes which are accepted as being indicative of malignancy are present, in more or less well-defined form, in leukemia. The most conspicuous of these changes are hyperchromatism which is due to increase in the size of the chromosomes, enlargement of the nucleolus, variation in the number of chromosomes, defects in the spindle during mitosis, and increased variability in the size of the cells and the nuclei. Obviously, the question whether there is any casual sequence among these cell abnormalities demands answer.

An inadequate, but, I hope accurate, review of the fundamental work of Caspersson, Darlington, Claude, and Thomas, will give some indication of the present position of the problem. Thus, it is known that nucleic acid and nucleoproteins play an outstanding part in cellular activities. Ribose nucleic acid is produced by the heterochromatic regions of the chromosomes, and is found in the nucleoli and in the cytoplasm. It is closely associated with the synthesis of the self-perpetuating proteins in the cell-body. Desoxyribose nucleic acid, which is produced during the prophase of mitosis, becomes attached to the chromosomes and is responsible for their reproduction. While this is happening, the nucleolus, with its store of ribose nucleic acid, dissolves and disappears. Then, when the chromosomes have divided and have reformed as daughter nuclei, their charge of desoxyribose nucleic acid is given up and is reconstituted as ribose nucleic acid in the freshly formed nucleoli.

In normal cells, the two nucleic acids are so balanced that chromosome reproduction and cytoplasmic synthesis are balanced, probably by the regulating action of heterochromatin. If this be so, increase of heterochromatin will lead to excessive nuclear synthesis and therefore, to an increased rate of nuclear division.

Endless and rather fruitless speculation along these lines is possible, but, even without departing far from solid experimental observations, something of importance can be inferred. For instance, Beadle showed that mutation in a single nuclear gene can induce polymytosis, but the observations briefly discussed above indicate that mutation in cytoplasmic elements may also cause great change of cellular characters. Then again, the existence of self-perpetuating elements in the cytoplasm (the plasmagenes of Darlington) throws some light on the characters of "viruses," because both plasmagenes and viruses depend for their continuance on a chemical equilibrium, and Potter alleged that the "cancer virus" is almost identical with an enzyme X, which is a complex of respiratory enzymes of the nature of a ribonucleoprotein.

The chemical and the virus theories of the origin of malignant conditions, among which leukemia must be included (at least on cytologic grounds), are thus found to be almost, if not entirely, unified.

These observations and similar reflections, together with further experimental work, form the basis of the urethane treatment of leukemia introduced by Haddow and Sexton, and investigated, by Paterson, Haddow and others. And one point that emerges very clearly is that nucleic acids are of outstanding significance in the leukemias (and probably in all forms of malignancy). This is strikingly shown by the action of *colchicine*, which was first employed in medicine for its action in gout (a malady in which the metabolism of purins is upset), was then observed to act on the bone-marrow, later was discovered to have a remarkable effect on mitosis (for instance, in inducing polymytosis in wheat), and is now known to have some effect in leukemias. And when the fairly common concomitance of gout and chronic myeloid leukemia is recollected, the skein of evidence, incriminating the purins, although still unravelled, seems to be fairly complete.

During experiments on the growth-inhibiting effects of urethane on animal tumors, Haddow and Sexton observed striking changes in the cells of the Walker rat carcinoma and a fall of the leukocyte count in some cases, and as there is little evidence that urethane is liable to cause aplasia of the marrow, it is preferable to benzol while being more efficacious than arsenic. This suggested the trial of the drug in leukemias, and it is not too much to assert that further therapeutic application of this substance has shown that it is probably the most satisfactory treatment for chronic myeloid leukemia now available.

Urethane remains effective when x-rays have failed, but seems to be the method of treatment indicated from the outset in most cases. But it is not to be supposed that the drug is in fact a cure for the disease.

The composition of the leukocyte-picture approaches normal, the red cells and hemoglobin rise, and the spleen retires behind the costal margin. And it appears that these results depend upon the action of urethane at the prophase of mitosis of the least differentiated stem-cells of the blood. There is, in fact, a redistribution of the nucleic acids, as shown by the Feulgen reaction. The way is thus open for the micro-chemist to find a new weapon for the even more fundamental treatment of the leukemias, but already urethane can often produce a prolonged period of clinically perfect remission.

THE USE OF URETHANE (ETHYL CARBAMATE) IN THE TREATMENT OF LEUKEMIA

A PRELIMINARY REPORT

By CHARLES H. WATKINS, M D , TALBERT COOPER, M D ,
AND HERBERT Z. GIFFIN, M D

HADDOW and Sexton¹ noted a coincidental depression of the leukocyte count during the course of observations on the effect of various forms of urethane on the growth of experimentally produced tumors in the rat. As a result, the various forms of urethane, principally ethyl carbamate, were subsequently utilized in the treatment of leukemias and other types of malignant disease by Paterson, Thomas, Haddow and Watkinson.² Encouraging results followed the administration of urethane in the majority of 13 cases of myelogenous leukemia and, to a lesser extent, in 9 cases of lymphatic leukemia. The most favorable response consisted of a reduction of the total leukocyte count to normal levels, production of a more nearly normal differential pattern, elevation of hemoglobin levels and diminution in the size of enlarged lymph nodes or spleen. These effects were sustained for variable periods, the longest period of observation recorded being eleven months. Symptoms of gastrointestinal irritation of mild to moderate degree rather commonly followed administration of the drug. Aplastic anemia developed in 2 cases, in one of which there was a fatal termination. In general, the results obtained were regarded as much like those following the use of the standard method of irradiation therapy.

The mode of action of urethane remains obscure. Kirschbaum and Lu³ observed that the administration of a single anesthetic dose of urethane to mice with myelogenous leukemia resulted in a drop, within twenty-four hours, in the total leukocyte count and in the appearance of many mature cells in the bone marrow. The number of mitotic figures in the myeloid cells of the marrow was decreased and it was suggested that maturation may have been secondary to inhibition of mitosis in blast cells. Johnson⁴ observed that urethane exerts an antisulfanilamide effect, similar to that of para-aminobenzoic acid, in work with certain strains of luminous bacteria. This would suggest that urethane's growth-inhibiting property may result from interference with utilization, in cellular metabolism, of some natural amine.

At the Mayo Clinic, clinical experience with urethane (ethyl carbamate) in the treatment of leukemic states now covers a period of approximately eight months. While the ultimate evaluation of this substance as a means of treatment for the leukemias obviously remains to be determined in the future, certain current observations may be of interest to those concerned in the management of these perplexing conditions.

RESULTS OF TREATMENT

Chronic myelogenous leukemia In 14 cases, urethane is now being used as the sole means of treatment. The patients in these cases have been under treatment for periods ranging from seven weeks to eight months. In all instances, the response to treatment thus far has been regarded as satisfactory and no supplementary measures have been required. There has been a consistent reduction in the total leukocyte count (table 1) accompanied by a parallel reduction in the degree of myeloid immaturity apparent in differential analysis of smears of the peripheral blood and sternal bone marrow. The erythrocyte count and hemoglobin values have either shown a significant increase or have remained virtually unchanged. In no instance has anemia or clinically significant thrombocytopenia developed during

TABLE 1—*Early Effects of Treatment of Chronic Myelogenous Leukemia with Urethane*

Urethane, Gm	Leukocytes per cubic millimeter of blood	
	Before treatment	Six weeks (average) after treatment
65	124,000	23,500
95	234,000	93,600
105	155,000	18,600
68	163,000	21,100
87	145,000	25,600
110	307,000	26,000
91	147,000	46,000
75	260,000	13,000
40	137,000	9,590
52	130,000	23,400
168	210,000	84,000
21	164,000	8,300
85	118,000	14,750
72	117,000	42,100

the course of treatment. Splenomegaly has been consistently and rapidly diminished in degree, although in no case has a previously palpable spleen disappeared entirely. The degree of response apparently was not affected by the initial level of the total leukocyte count, the duration of the illness or the amount of previous irradiation therapy.

A satisfactory response to treatment was achieved in three to ten weeks (average six weeks) following the administration of 21 to 168 Gm of urethane (average 80 Gm). The drug was usually administered in a dosage of 1 Gm three times a day at the outset. This amount was reduced to 1 to 2 Gm daily as the leukocyte count descended. The primary fall in the leukocyte count usually occurred seven to fourteen days after the institution of therapy and was often preceded by a transient elevation. However, in 2 cases, twenty-one to twenty-eight days of treatment was required to produce the initial depression of the leukocyte count.

The dosage necessary to maintain the leukocyte count at relatively normal

levels (less than 20,000 per cu mm of blood) has been highly variable, although for the 2 patients under observation for the longest periods, 0.5 to 1.0 Gm daily has been found adequate. Weekly leukocyte counts are necessary in determining the long-term needs in the individual case, the amount of urethane administered being increased or reduced accordingly. An effort has been made to maintain the total leukocyte count at 20,000 or less per cu mm and the drug has been temporarily discontinued when the total leukocyte count has been less than 10,000 per cu mm. No cases of chronic leukopenic myelogenous leukemia were included in this series.

On cessation of therapy, recurrence of leukocytosis with myeloid immaturity invariably occurred after variable periods of time.

Mildly to moderately severe symptoms of gastrointestinal irritation occurred in approximately one third of the cases but disappeared with continued administration of the drug, although a reduction in dosage was sometimes necessary. A direct relationship between the size of the daily dose and the frequency of gastrointestinal complaints was soon established and, in recent months, an amount in excess of 3 Gm daily has rarely been prescribed. No other toxic manifestations attributable to the drug were observed in this series.

Acute myelogenous leukemia Urethane was administered in 2 cases for periods of ten to fourteen days with no significant change in the clinical course, although there was some decrease in the degree of myeloid immaturity in smears of the peripheral blood and sternal marrow.

Chronic lymphatic leukemia The drug was administered, in apparently insufficient amounts, in 2 cases. There was no appreciable effect on the total leukocyte count.

Acute lymphatic leukemia Urethane has been administered for periods of one to three weeks in 8 cases. In three instances, there was a precipitous fall in the total leukocyte count, but in none was the general clinical course materially influenced.

Acute monocytic leukemia In 2 cases, treatment of one to three weeks' duration produced no measurable hematologic or clinical change.

COMMENT

Our experience would indicate that urethane can be expected to produce a temporary hematologic remission in cases of chronic myelogenous leukemia. This remission is similar, in superficial characteristics, to that observed after irradiation therapy. There is, at the present time, no indication that urethane offers more than other agents which are used palliatively in this disease. However, by virtue of its convenience of administration and the possible advantage of controlled, continuous action, urethane may be found preferable to other methods of treatment in use at the present time.

We have had insufficient experience with the use of urethane in the treatment of chronic lymphatic leukemia to warrant an opinion as to its efficacy. However, the reported experiences of Paterson and co-workers² would seem to justify continued use of the substance in such cases.

While, like irradiation therapy, urethane may produce a rapid decrease in the number of immature leukocytes circulating in the blood in some cases of acute

myelogenous and lymphatic leukemia, there is no evidence to suggest that the usual course of these conditions has been beneficially influenced

Despite the absence of serious toxic effects encountered in this series to date, the potential production of aplastic anemia and other complications⁵ by this substance must be kept in mind

SUMMARY

Limited experience with the use of urethane in the treatment of leukemia indicates that this substance presents a considerable promise as a palliative agent in chronic myelogenous leukemia. It has no apparent value in the treatment of acute leukemia.

Further extensive observation will be necessary to provide a true measure of the clinical usefulness of this preparation.

URETHANE THERAPY IN LEUKEMIA

By ADOLPH J. CRESKOFF, M D , THOMAS FITZ-HUGH, JR , M D , AND
JOHN W. FROST,* M D

THE purpose of this paper is to report the results of urethane therapy of the leukemias, based on a study of 24 patients

In April, 1946, Haddow and Sexton¹ described the influence of various carbamic esters on experimental rat cancers. Ethyl carbamate (urethane) yielded the best results. It alone produced inhibition of tumor growth and fibrous replacement of the cancerous rat tissue. For this reason, and since urethane is relatively nontoxic for humans and is easily obtainable, the experiments were transferred to human subjects with carcinoma of the breast and other malignancies. The results were generally disappointing. It was, however, noted that a few of these patients developed leukopenia while taking urethane. This observation motivated, in 1943, the first clinical trial of the effects of urethane in leukemia and allied disorders.

In May, 1946, Paterson, Haddow, Thomas, and Watkinson² reported the results of urethane treatment of 32 leukemic patients. The drug was administered orally in an average dose of 3 to 4 grams daily. The drug proved "effective" in approximately one-third of the patients, producing in this "favorable group" reduction in size of enlarged spleens and of lymph nodes and causing reversion of the blood picture to more normal values. These workers found the urethane effect to be approximately equal in value to that of standard deep x-ray therapy in a control series of similar cases. Of their 32 urethane-treated patients, 19 had myelogenous leukemia, and 8 of these were benefited. Clinical and hematologic remissions were maintained for periods of 2 to 6 months. Of 13 patients with lymphatic leukemia, 2 responded similarly. The remaining 22 were either partially improved, could not tolerate the drug, or died during treatment.

Toxic side effects observed by the British workers included nausea, drowsiness, anorexia, diarrhea, and suggestive evidence of marrow hypoplasia.

On the basis of these results, parallel observations were started at the Hospital of The University of Pennsylvania in June, 1946. At the time of this writing (September, 1947) we have treated a total of 27 patients suffering from leukemia. Three of these are too recently treated for accurate evaluation. Our report is based on the remaining 24.

Dosage and methods of administration. The usual dose of urethane was 4 grams (range 2 to 6 Gm) daily, given in solution, orally. A mixture similar to that used by the British group was employed in most of the patients.

Urethane	30
Syrup of orange	50
Chloroform water to	300
(each 5 cc contains 0.5 grams urethane)	

From the Hematological Section of the Medical Clinic, Hospital of the University of Pennsylvania, Philadelphia

This work has been aided by a grant from the Eli Lilly Company

* Eli Lilly Fellow in Hematology

This mixture was administered (1 to 4 teaspoonsful) after each meal, in a small amount of some flavored carbonated beverage or fruit juice. In a smaller group of patients, the drug was administered in 0.5 Gm gelatin capsules. This method of administration proved to be impracticable because of the hydroscopic nature of the urethane. Rectal suppositories (each 0.5 Gm urethane in cocoa butter) were tried in 2 patients who developed nausea from oral medication. Rectal irritation occurred within a few days, requiring cessation of this method of administration.

In one patient (Case 4) with a large leukemic tumor, 50 per cent urethane ointment was employed locally, in conjunction with oral urethane medication. The ointment was prepared by melting urethane crystals and incorporating the solute in aquaphor. The leukemic tumor disappeared under this therapy, although the patient died subsequently.

Urethane intravenously has been our most recent mode of administration. Ampoules* containing 1 or 2 Gm urethane in 20 cc of normal saline solution or distilled water, were mixed with 200 cc of normal saline and the resulting mixture was administered in 15 to 30 minutes intravenously, without untoward reactions.

Clinical material The results in 24 leukemic patients are reported. Table 1 indicates the distribution of types of leukemia.

RESULTS OF URETHANE THERAPY

Chronic Myelogenous Leukemia

Our results in 7 cases of chronic myelogenous leukemia are summarized in table 2. It is to be noted that in 4 cases, urethane therapy was started during terminal stages of the disease, after resistance† to x-ray therapy had been established. Two cases are regarded as showing satisfactory clinical and hematologic remissions after urethane therapy. Case 4 is of special interest because of a successful remission maintained despite the complication of pregnancy which is now in its seventh month and is proceeding uneventfully.

CASE REPORTS

Case 4 This white female, age 30, first noted weakness, nausea, and abdominal enlargement during the latter months of 1945. When first examined on December 12, 1946, she exhibited massive splenomegaly (19 cm below the left costal margin), and slight liver enlargement. Blood Hgb 8.38 Gm, WBC 320,000, immature myeloid leukocytes‡ 34 per cent. Urethane, 3 Gm daily, in solution orally, was started on December 14, 1946, and was increased to 4 Gm daily five days later. By the forty-third day of treatment,

* Prepared according to our specifications regarding sterility, isotonicity and pH corrections by Dr F. B. Peck, Eli Lilly Laboratories.

† The term "x-ray resistance" is here employed without implications of any kind except to designate the fact that our own Department of Roentgenology, employing the techniques and dosages judged by this Department to be the best under the circumstances, had failed to obtain a remission from one or more recent courses of therapy which formerly in the same patient had produced a remission.

‡ The term "immature myeloid leukocytes" refers to the combined percentage of myelocytes, promyelocytes, and myeloblasts.

the spleen measured 11 cm and the blood count was Hgb 9.9 Gm , WBC 11,000, immature myeloid leukocytes none The drug was continued until March 22, 1947 (ninety-eighth day), when the spleen measured 5 cm and the blood showed Hgb 13.0 Gm , WBC 10,000, immature myeloid leukocytes 3 per cent The patient was symptom-free

This patient conceived while on urethane therapy When last seen (Aug 26, 1947), she was asymptomatic, vigorous, and in the seventh month of pregnancy The spleen was palpable 6 cm below the costal rim Blood Hgb 11.4 Gm , WBC 35,000, immature myeloid leukocytes 7 per cent

Case 9 White female, age 38 Urethane was first administered during the late stage of chronic myelogenous leukemia of over six years' duration The patient had failed to respond to her most recent (seventh) course of irradiation She showed cachexia, lymphadenopathy, and an enormous spleen which al-

most filled the abdomen Blood Hgb 7.97 Gm , WBC 149,000, immature myeloid leukocytes 34 per cent Urethane, 4 Gm daily, in solution orally, was started on October 25, 1946, and continued until the patient expired on December 23, 1946 Blood Hgb 8.02 Gm , WBC 76,000, immature myeloid leukocytes 31 per cent

Case 10 This white male, age 46, was a terminal, much treated case of chronic myelogenous leukemia of over three years' duration He was readmitted to the hospital in an acute relapse phase of his disease Urethane, 1 Gm daily, in solution orally, was given for thirteen days with a fall in the leukocyte count from 103,000 to 9,000 No clinical improvement occurred and the patient died within two weeks after stopping the drug

Case 17 A white male, age 65, was a terminal case of subacute myelogenous leukemia of one year duration, resistant to irradiation He was unable to tolerate an adequate dose of urethane either orally or by suppository A leukemic tumor of his forehead shrank in size and finally disappeared after application of 50 per cent urethane-aquaphor ointment He died soon thereafter

Case 20 This white female, age 50, was a leukemic of four years duration. After numerous courses of irradiation she was finally considered x-ray resistant. She was cachectic, anasarcatous, and exhibited massive enlargement of lymph nodes, spleen, and liver. Blood Hgb 4.95 Gm, WBC 395,000, immature myeloid leukocytes 52 per cent. Urethane, 2 Gm, then 4 Gm daily, intravenously was started May 25, 1947, and continued until she died suddenly on June 1, 1947, soon after thoracentesis. On May 31, 1947, she had been clinically unimproved, although her white blood count had dropped to 22,000 on this date.

Case 22 This white male, age 63, had suffered weakness and weight loss for three years. He had just completed a short course of Fowler's solution, when first examined on June 13, 1947. He presented fever

FIG 1. CASE 4, CHRONIC MYELOGENOUS LEUKEMIA IN A WHITE FEMALE, AGE 30 (□ = PER CENT BLASTS, PROMYELOCYTES, AND MYELOCYTES, ○ = SPLENIC SIZE IN CM)

pallor, petechiae, edema, and moderate splenic and lymph node enlargement. Blood Hgb 7.59 Gm, WBC 63,000, immature myeloid leukocytes 33 per cent, Platelets 45,000. Intravenous urethane 2 Gm was given on June 19, 1947 (WBC 55,000), and was increased to 3 Gm daily the following day. On June 29, 1947, the drug was stopped after a total of 29 Gm intravenously. The patient was unimproved. Blood Hgb 7.5 Gm, WBC 14,000, immature myeloid leukocytes 13 per cent. Transfusions were ineffective. Radioactive phosphorus was given, but the patient died within two weeks.

Case 24 This white female, age 51, was known to have leukemia of four years duration. She had had several excellent x-ray induced remissions. When seen in the clinic, May 8, 1947, she complained of recent epistaxis and weakness. Her general condition seemed good. The lymph nodes and spleen were not enlarged. Blood Hgb 12.4 Gm, WBC 50,000, immature myeloid leukocytes 17 per cent, Platelets 142,000. Over the next forty-four days, a total of 116 Gm urethane, in solution orally, was administered. On June 27, 1947, she felt entirely well. Blood Hgb 13.2 Gm, WBC 5,100, immature myeloid leukocytes 2 per cent, Platelets 256,000. When last seen Aug 12, 1947, she was clinically well. Blood Hgb 13.7 Gm, WBC 26,000, immature myeloid leukocytes 10 per cent.

Chronic Lymphatic Leukemia

Our results in 7 cases of chronic lymphatic leukemia are summarized in table 3. It is of interest that the first case we treated with urethane (Case 1) has now enjoyed an entirely satisfactory remission of slightly over one year's duration.

CASE REPORTS

Case 1 This white female, age 57, first noted weakness, and left-sided heaviness in May, 1946. When first examined by us on June 20, 1946, massive splenomegaly and slight lymphadenopathy were found. Blood Hgb 12.2 Gm, WBC 700,000, lymphocytes 96 per cent, Platelets 118,000. Urethane 2 Gm daily, in solution orally, was started on June 24, 1946, and increased to 4 Gm daily eleven days

ater. Marked shrinkage in size of the spleen was apparent after forty-three days of treatment. On September 3, 1946 (seventy-second day of treatment), after a total of 283 Gm of urethane, treatment was stopped. The patient was entirely symptom free, the spleen was barely palpable. Blood Hgb 11.41 Gm, WBC 4,500, lymphocytes 53 per cent. When last seen on August 29, 1947, the patient was in good condition. The spleen again showed slight enlargement. Blood Hgb 12.4 Gm, WBC 32,000, lymphocytes 92 per cent.

Case 3 This white female, age 54, was found to have asymptomatic chronic lymphatic leukemia in September, 1945, and a brief course of irradiation therapy was given. She was first seen in this clinic December 7, 1946. She was still asymptomatic, there was no lymphadenopathy and the spleen was moderately enlarged. Blood Hgb 12.95 Gm, WBC 102,000, lymphocytes 87 per cent. Urethane 3 Gm daily, in solution orally, was started. The drug was stopped on February 16, 1947 (seventy-sixth day of treatment), after a total dose of 191 Gm, her spleen was impalpable, she was still symptom free, and her blood count was Hgb 12.5 Gm, WBC 6,400, lymphocytes 66 per cent.

The drug was resumed on April 27, 1947, because of a rise in the leukocyte count to 19,800. On May 19, 1947, after a total dose of 69 Gm, urethane was again discontinued when her blood count was Hgb 12.0 Gm, WBC 6,200, lymphocytes 40 per cent. When last seen on August 15, 1947, the patient was still asymptomatic, her spleen was barely palpable and her blood count was Hgb 33.42 Gm, WBC 11,000, lymphocytes 79 per cent.

Case 6 This white male, age 59, was found in a routine blood count to have 43,000 leukocytes, with 62 per cent lymphocytes. He was asymptomatic, with shotty lymphadenopathy and a barely palpable liver and spleen. Although he required no specific treatment at this time, urethane was started on July

FIG 2 CASE 2, CHRONIC LYMPHATIC LEUKEMIA IN A WHITE FEMALE, AGE 57
(□ = PER CENT LYMPHOCYTES)

27, 1946, in a dosage of 2 Gm daily, in solution orally. Blood Hgb 14.5 Gm, WBC 58,000, lymphocytes 89 per cent. No effect of the drug could be detected after 299 days of treatment, (total dose 683 Gm), and it was stopped on May 15, 1947, when the blood count was Hgb 13.0 Gm, WBC 21,000, lymphocytes 93 per cent.

This case suggests that low-grade chronic lymphatic leukemia is resistant to urethane in a dosage of 2 Gm daily.

Case - This white male, age 67, was hospitalized in March, 1944 for prostatic resection. At this time the blood picture of chronic lymphatic leukemia was found. He received a course of irradiation therapy in October, 1945. When first seen in the clinic on November 12, 1946, he was acutely ill, with findings of massive lymphadenopathy, splenomegaly, and marked pulmonary infiltration. Blood Hgb 7.5 Gm.

WBC 233,000, lymphocytes 99 per cent, Platelets 320,000 Urethane, 4 Gm daily, in solution orally, was started on November 16, 1946 On January 18, 1947 (sixty-second day of treatment), after a total dose of 225 Gm , the drug was stopped when the blood count was Hgb 6.9 Gm , WBC 5,600, lymphocytes 93 per cent The patient had become progressively worse He died in cardiac failure on January 31, 1947, despite apparent "improvement" in the abnormal lymphocytosis

Case 8 This white male, age 61, had sudden severe pain in the left side of the abdomen in November, 1946 Examination disclosed generalized lymphadenopathy, marked splenomegaly, and marked lymphocytosis Blood Hgb 11.4 Gm , WBC 238,000, lymphocytes 98 per cent Urethane was started on November 9, 1946, 2 Gm daily, in solution orally Dosage was increased to 4 Gm daily on November 27,

FIG 3 CASE 3, CHRONIC LYMPHATIC LEUKEMIA IN A WHITE FEMALE, AGE 54

1946, and to 6 Gm daily on December 5, 1946 Weakness, marked sweating, and insomnia developed On January 6, 1947, lymph nodes were estimated 80 per cent reduced in size but the size of the spleen was unchanged Blood Hgb 11.1 Gm , WBC 400,000 The dosage of urethane was decreased to 4 Gm daily until January 20, 1947 (sixty-third day of treatment) when it was discontinued (total dose 297 Gm) Blood Hgb 12.2 Gm , WBC 293,000, lymphocytes 97 per cent X-ray therapy was instituted with prompt fall in the leukocyte count, but little change in size of lymph nodes or spleen When last examined on August 25, 1947, moderate splenomegaly and lymph node enlargement were found His blood count showed Hgb 33.6 Gm , WBC 38,000, lymphocytes 93 per cent

This case is judged a urethane failure Although regression in lymph node size occurred there was no improvement in the splenomegaly or in the blood picture

Case 13 This white male, age 52, presented generalized exfoliative dermatitis, lymphadenopathy, and lymphocytosis, diagnosed as leukemia cutis, of six months duration Urethane, 4 Gm daily, in solution

orally, was started on January 7, 1947 Blood Hgb 13.0 Gm, WBC 44,000, lymphocytes 83 per cent. No change in the patient's clinical condition was apparent when the drug was stopped 136 days later (total dose 521 Gm). Blood Hgb 11.5 Gm, WBC 21,000, lymphocytes 33 per cent.

TABLE 4—*Acute Leukemia*

Case	Original Status	WBC Start U	U (grams) U (days)	WBC End U	Result
#2 W 50 F	Untreated Monocytic	35,000	60 14	1,100	Good initial, but relapse 3 mo
#5 W 53 F	Untreated Myelogenous	79,000	26 10	8,000	Poor Died
#11 W 14 F	Untreated Myelogenous	240,000	64 20	250,000	Poor Died
#12 W 12 F	Untreated Aleukemic Lymph	1,800	14 7	900	Poor Died Aplastic mar- row
#14 W 42 M	Untreated Myelogenous	77,000	48 8	49,000	Poor Died

#18 C 3 F	Untreated Myelogenous	56,000	26 13	300	Fair for 1 mo then re- lapse Marked decrease in size of kidney masses
#19 C 38 M	Untreated Myelogenous	110,000	67 17 (I V)	9,500	Left hospital No follow- up
#21 W 36 M	Untreated Lymphatic	200,000 39,000	28 14 (P O) 106 24 (I V)	39,000 132,000	Poor Died
#23 W 5 F	Untreated Myeloblastic	132,000	3 2 (I V)	2,700	Poor Died

Case 16 This white male, age 45, noted enlargement in circumference of neck in December, 1946. When first seen on January 18, 1947, he presented generalized lymphadenopathy and moderate splenomegaly. Blood Hgb 13.99 Gm, WBC 265,000, lymphocytes 93 per cent, Platelets 112,000. Urethane, 3 Gm daily, orally, first in solution, then in capsules was started on January 27, 1947. The dose was soon increased to 4 Gm daily. By March 20, 1947 (fifty-first day of treatment), dangerous symptoms of drowsiness, weakness, anorexia, fever, petechiae, mucosal bleeding, and hematuria appeared. Blood Hgb 7.52 Gm, WBC 51,000, lymphocytes 93 per cent, Platelets 50,000. On April 1, 1947 (sixty-third day of treatment), after a total of 218 Gm, the drug was stopped. No significant changes in lymph node or splenic size were

demonstrable. Multiple transfusions, followed by cautious x-ray irradiation produced slow improvement with cessation of hemorrhagic phenomena and marked reduction in the size of lymph nodes. The blood picture improved, and when last seen on August 25, 1947, his blood count showed Hgb 13.20 Gm, WBC 81,000, lymphocytes 79 per cent, Platelets 64,000.

This case is obviously another urethane failure. It is possible that the drug produced critical hypoplasia of erythrocytic and megakaryocytic elements in the bone marrow.

Acute Leukemias

Table 4 summarizes the results in 10 cases of acute leukemia of various types. In most cases, a prompt fall in the total leukocyte count followed urethane treatment. Evanescent clinical improvement occurred in 4 patients (Cases 2, 15, 18, 19). Final information regarding 2 patients in this series is not available. All other patients died during or soon after urethane therapy.

CASE REPORTS

Case 2 This white female, age 40, had acute monocytic leukemia (Naegeli type) with fever, gingival necrosis, and extensive intracutaneous and mucosal bleeding of 2 weeks duration. Urethane, 4 Gm daily, in solution orally, was started on August 21, 1946. Blood: Hgb 7.2 Gm, WBC 35,000, immatures (promonocytes and monoblasts) 64 per cent. A total of 60 Gm was given during the next ten days with rapid fall in leukocytes to 1,100, then to 650/cu mm. Progressive anemia paralleled the fall in leukocytes. On September 4, 1946, the blood count showed Hgb 1.38 Gm, WBC 1,300, immatures 26 per cent. Despite these desperately low blood levels the patient felt improved, the gums healed and bleeding ceased. There was gradual improvement and when the patient was sent home on October 4, 1946, the blood count was Hgb 4.95 Gm, WBC 2,400, immatures 36 per cent.

It is noteworthy that sternal aspiration soon after termination of therapy showed striking reduction in numbers of blast cells as compared with the original aspiration.

Continued improvement was maintained. On December 4, 1946, the blood count showed Hgb 10.4 Gm, WBC 4,700, immatures none (commercial clinical laboratory). In mid-January, 1947, the patient fell, injured her mouth and apparently was precipitated into an acute relapse. Urethane, 4 Gm, in solution orally, was resumed on January 23, 1947, when the blood count was Hgb 9.76 Gm, WBC 70,000, immatures 69 per cent. The patient developed diffuse bronchopneumonia and died February 6, 1947. Blood: Hgb 2.9 Gm, WBC 2,300.

This was our first experience with the swift effect of urethane on the leukocyte count observed subsequently in most of our cases of acute leukemia. The partial remission in this patient encouraged further trials in this form of leukemia.

Case 5 White female, age 53. Acute myelogenous leukemia. Urethane, 2 to 4 Gm daily, in solution orally, was started on June 30, 1946 when the blood showed Hgb 12.4 Gm, WBC 79,000, immatures (promyelocytes and myeloblasts) 82 per cent. Four days later the patient exhibited a phlebothrombosis of the right leg. On July 9, 1946, urethane was discontinued (total dose 26 Gm). Blood: Hgb 9.2 Gm, WBC 8,000. On July 23, 1946, the leukocyte count rose to 31,000 and urethane, 4 Gm daily, orally was resumed. The patient died suddenly of pulmonary embolism, July 31, 1946, after a second course of 20 Gm of urethane when the blood count was Hgb 7.9 Gm, WBC 16,000.

Case 11 White female, age 14. This patient had acute myelogenous leukemia of two weeks duration, with generalized lymphadenopathy, hepato-splenomegaly, gingivitis, mucosal and intracutaneous bleeding. On December 4, 1946, the blood count showed Hgb 12.2 Gm, WBC 360,000, blast cells 89 per cent. A total dose of 68 Gm of urethane was given between December 30, 1946 and January 7, 1947, when the patient died after a progressively downhill course. Blood: Hgb 6.2 Gm, WBC 250,000.

Case 12 White female, age 12. This patient had acute aleukemic lymphatic leukemia with hemolytic staphylococcus aureus septicemia. Urethane, 4 Gm daily, in solution orally was started on April 7, 1947.

Blood Hgb 6.27 Gm, WBC 1,800, blast cells 82 per cent. Urethane was discontinued April 14, 1947 (total dose 14 Gm), when the blood count showed Hgb 6.6 Gm, WBC 900. Death occurred April 22, 1947, despite multiple transfusions and penicillin therapy.

Sections of marrow obtained at autopsy showed almost complete aplasia in contrast to the initial sternal marrow appearance of acute lymphoblastic leukemia.

FIG. 4. BONE MARROW OF CASE 2 BEFORE TREATMENT.

Case 14 White male, age 42. This patient had acute myelogenous leukemia and was moribund on admission. He was given 6 Gm urethane daily, in solution orally, for eight days without detectable effect clinically or hematologically. The patient died August 2, 1947 while still under therapy.

Case 15 White male, age 15. Acute myelogenous leukemia. He had received 115 Gm urethane orally in 32 days, while in another hospital, with a fall in leukocytes from 221,000 to 19,300 but without clinical improvement.

Urethane, 3 to 4 Gm daily, orally in solution, was reinstituted March 1, 1947. Blood Hgb 13.8 Gm, WBC 74,000, immatures (blasts) 96 per cent. Because of severe nausea, vomiting, and diarrhea the drug was stopped March 8, 1947 (total dose 141 Gm). WBC 125,000. Irradiation therapy was started March 10, 1947 and given daily until discharged at his request on March 19, 1947, when his blood count showed Hgb 7.4 Gm, WBC 173,000. This patient died two weeks later.

Case 18 * Colored female, age 3 Acute myelogenous leukemia This patient had been ill for one month The outstanding physical finding was the presence of huge bilateral renal masses Urethane, 2 Gm , daily in solution orally, was started March 12, 1947, when the blood count was Hgb 4.3 Gm , WBC 41,000, immatures (blast cells) 40 per cent By March 19, 1947, the renal masses had decreased markedly in size (by palpation and urography) The drug was stopped on March 24, 1947, when the blood count showed Hgb 4.6 Gm , WBC 1,100, immatures none The patient seemed temporarily improved, but relapsed and died one month later

FIG 5 BONE MARROW OF CASE 2 AFTER TREATMENT

Case 19 Colored male, age 38 Acute myelogenous leukemia Urethane, 3 Gm intravenously was started on May 9, 1947, and increased to 4 Gm daily the following day Blood Hgb 2.11 Gm , WBC 110,000, immatures (promyelocytes and myeloblasts) 90 per cent On May 25, 1947, after a total of 67 Gm intravenously, the patient showed improvement in strength and a 50 per cent decrease in the size of the lymph nodes The blood count at this time showed Hgb 5.9 Gm , WBC 9,500, immatures 73 per cent After receiving 2,000 cc of whole blood the patient was discharged June 10, 1947 when the blood count showed Hgb 7.8 Gm , WBC 5,500, immatures 69 per cent It has been impossible to obtain further information regarding this patient

* This case observed at Philadelphia General Hospital, courtesy of Dr Paul Gyorgi

Case 21 White male, age 30 Acute lymphatic leukemia This patient had been given 28 Gm of urethane in fourteen days, elsewhere, with fall in leukocyte count from 200,000 to 39,000 He was admitted to the Hospital of The University of Pennsylvania on May 26, 1947, in poor condition, and given preliminary dose of 3 Gm urethane, intravenously at which time the blood count was Hgb 8.8 Gm, WBC 21,000, immatures (prolymphocytes and lymphoblasts) 55 per cent The dose was changed to 4 Gm daily on May 27, 1947, and again to 6 Gm daily on June 13, 1947 Blood Hgb 6.9 Gm, WBC 109,000, immatures 99 per cent A total of 106 Gm urethane, intravenously, had been given over a twenty-four day

FIG 6 CASE 19, ACUTE MYELOGENOUS LEUKEMIA IN A NEGRO MALE (□ = PER CENT BLASTS AND PROMYELOCYTES)

period when this patient died June 20, 1947 The blood count then was Hgb 8.6 Gm, WBC 132,000 The patient had also received 5,000 cc of whole blood during his hospital stay

Case 23 White female, age 5 Acute myelogenous leukemia One Gm urethane, intravenously, was given June 8, 1947, when the blood count was Hgb 7.02 Gm, WBC 132,000, blasts 90 per cent On June 9, 1947, 2 Gm urethane was given intravenously This was followed by a sudden rise in temperature to 105.2 F, rectally Urethane therapy was discontinued On June 12, 1947, marked diminution in splenic size was noted, and the blood count was Hgb 6.13 Gm, WBC 2,700 The patient died June 17, 1947 with a Hgb of 4.75 Gm, and a WBC of 750 cu mm

Summary of Results

It is apparent from the data presented above that satisfactory remissions as a result of urethane therapy occurred in 4 cases (1, 3, 4, 24) of our combined number of 24 cases. It is worthy of emphasis that of these 24 cases, at least 14 (Cases 9, 10, 17, 20, and all acute leukemias) and possibly 2 others (Cases 7 and 21) would, in our opinion, have proved hopelessly refractory to any known method of treatment of leukemia. It may be significant also that although urethane was withdrawn in Cases 8 and 13 because of poor response, these patients subsequently responded poorly to irradiation and radioactive phosphorous, respectively.

If the experimentally treated 4 terminal cases of chronic myelogenous leukemia are omitted from consideration, it is apparent that urethane produced a satisfactory result in 2 of the 3 remaining cases. Adequate response was obtained in 2 of 7 cases of chronic lymphatic leukemia. It becomes evident that of 10 "fair" cases of chronic leukemia, urethane was successfully used in 4.

DRUG EFFECTS

Toxicity Nausea has been the predominant symptom of intolerance. Approximately 50 per cent of our patients exhibited mild or severe nausea commencing at any time during the course of oral administration of the drug. In a few cases, nausea was sufficiently severe to warrant interruption or cessation of treatment. Lesser toxic manifestations have been vomiting, anorexia, excessive sweating, diarrhea, and drowsiness.

The most dangerous toxic manifestation has been the appearance of evidence suggesting depression of all marrow elements (Cases 12, 16). Whether or not urethane produced or contributed to this effect, it is important to be wary of abrupt falls in erythrocyte or leukocyte levels during the period of urethane administration. It is significant that 2 patients in Paterson's series exhibited similar hypoplastic changes. Particular caution is advisable when leukopenic leukemia is under treatment, on the basis of Case 12. Rapidly developing anemia, in our experience, calls for immediate cessation of urethane therapy.

Urethane administered intravenously has produced only minimal side effects, such as transitory drowsiness, and transitory elevation of temperature. No local irritative phenomena have been observed. Particularly gratifying has been the absence of nausea, suggesting that the occurrence of this symptom after oral administration is due to gastric irritation. It is possible that enteric coated capsules or tablets may circumvent such nausea, and trials with such preparations are in progress.

Rapidity of effect The time required for a definite reduction in the leukocyte count (to 15-20,000) in favorable chronic cases averaged forty-eight days when the drug was given by mouth. In the acute leukemias, the effect was much more rapid, averaging ten days. It is believed that intravenous administration of urethane will produce effects more quickly than the above mentioned periods, although our data are as yet insufficient to establish this point.

Mode of action The manner and site of action of urethane are entirely unknown.

Haddow and Sexton¹ offer speculation regarding the possible action of urethane in remedying some deficiency in the process of leukocytic maturation in leukemia

Basal metabolism and blood chemistry In a small number of patients with chronic forms of leukemia, we observed that the basal metabolic rate fell in proportion to the decline in the total white cell count during urethane therapy

Marked reduction in elevated levels of blood uric acid was also noted in a few of our cases during therapy Case 19 had a blood uric acid of 11.3 mg per 100 ml on admission, which fell to 3.8 mg per 100 ml at the end of urethane therapy when the white blood count was 8,000 Case 4 had a reduction of blood uric acid from 8.9 mg per 100 ml to 4.2 mg per 100 ml while under urethane therapy

Blood urea nitrogen determinations were made before, during, and after urethane administration in 10 of our cases Elevation of the level of blood urea nitrogen occurred in no case during full urethane dosage

Blood levels of urethane have not been obtained A method of estimation has recently been published by Archer et al.³

DISCUSSION

Urethane adequately administered in cases of chronic leukemia frequently produces a marked reduction in the total leukocyte count (83.3 per cent of our series) In fully responsive, favorable cases definite clinical improvement gradually follows Splenomegaly is reduced, enlarged lymph nodes become smaller, and a feeling of betterment is expressed The hemogram assumes a more normal appearance in its entirety Unfortunately, in a larger number of cases the fall in the leukocyte count is a spurious improvement In such cases, visceral pathology and anemia may fail to improve or may grow worse, and the patient may exhibit progressive deterioration Continued administration of the drug in such instances may lead to rapid clinical deterioration It is generally advisable to suspend the drug if clinical improvement fails to appear within one week after a satisfactory rate of fall of the leukocyte count has appeared It is furthermore probably advisable to discontinue urethane if no significant fall in the white cell count has occurred within sixty days from the start of treatment

It is impossible, from our small series of cases, to offer definite criteria for selection of patients for urethane treatment It seems likely (in agreement with Pater-son et al.²) that chronic myelogenous leukemia responds better to urethane than does the lymphatic variety The drug has proved of little value in the acute leukemias, although further trials are justifiable in view of the swiftly fatal outcome of this form of leukemia

No information is as yet available as to the possibility of inducing repeated remissions in chronic leukemia with urethane, and if so, whether these can then be followed by successful repetitions of x-ray therapy If this should prove the case, then prolongation of the leukemic life-span as well as amelioration of symptoms may be possible In this regard it may be mentioned that in Cases 3 and 24, urethane successfully induced remissions after relapse from previously successful x-ray therapy Conversely, in 2 other cases (8 and 16), x-ray therapy successfully followed urethane failures This is in accord with the observation of the British

workers that urethane and irradiation therapy are not mutually exclusive in effect. Our evidence does indicate strongly that urethane is without clinical effect in terminal, long standing, repeatedly irradiated cases of chronic leukemia.

It is our impression that urethane will prove to be an occasionally useful adjunct in the management of chronic leukemia. The low cost and convenience of administration, in comparison with irradiation therapy are strong points in favor of this drug.

It is the opinion of the authors that in the treatment of leukemia in general, urethane is less consistent in effect than standard methods of irradiation therapy, and more consistent and more efficient than such modalities as Fowler's solution, benzol, and colchicine.

Our results, while not as striking, generally confirm the findings reported by Paterson and her co-workers. Urethane deserves further trial in the treatment of leukemias of all types.

SUMMARY

- 1 The results of urethane therapy in 24 cases of leukemia are described.
- 2 The average daily dose is 4 Gm orally or intravenously.
- 3 The drug is irregularly effective. Chronic myelogenous leukemia appears more responsive than the lymphatic variety.
- 4 Acute leukemias are not significantly altered in course by urethane.
- 5 Urethane produces a fall in the total leukocyte count in a majority of all types of leukemia. Clinical improvement does not necessarily follow.
- 6 Nausea is the most frequent side effect of urethane therapy. Possible marrow aplasia is the most dangerous toxic effect.
- 7 Urethane is of definite, but of limited value in the treatment of chronic leukemia. In some instances, it compares favorably with x-ray therapy, but in general, it is less dependable, particularly in its frequent failure to induce optimum return of normal red cell and platelet values, and optimum regression of organ infiltration.

THE EFFECT OF URETHANE ON THE NUCLEAR MORPHOLOGY OF CELLS OF THE GRANULOCYTE SERIES AS OBSERVED IN MARROW CULTURES AND LEUKEMIC BLOOD

By EDWIN E. OSGOOD, M.D., AND I. T. CHU, M.D.

INTEREST in urethane ($\text{NH}_2 \text{CO OC}_2\text{H}_5$) and related carbamic acid esters in the treatment of metastatic malignant tumors and leukemias has been greatly stimulated by the report of Haddow and Sexton¹ on the effects of urethane on tumors in experimental animals, and of Paterson, Haddow, Thomas and Watkinson² on urethane therapy of human leukemias and malignant tumors. They demonstrated striking decreases in the leukocyte count and spleen size in certain patients with granulocytic or lymphocytic leukemias and in the size of metastatic nodules in a small proportion of patients with other malignant tumors. The observations of Paterson, Haddow, Thomas and Watkinson² have been confirmed by Goodman and Lewis³ and by the authors at the University of Oregon Medical School.

Although urethane has long been in use as a narcotic and there is much literature on the action of the urethanes and related karyoklastic and karyokinetic poisons on the cells of lower forms of life,⁴ we were unable to find any reference to morphologic changes produced by urethane in the nuclei of human cells.

The present study, using the technic of human marrow culture,⁵ was undertaken as part of a long-term investigation of the factors influencing the fundamental phases of cell growth, namely, increase in size, mitotic and amitotic division, differentiation, and life span. This paper will be limited to the morphologic changes in cells of the granulocyte series produced by the action of urethane. Quantitative data on the comparative effects of urethane and methyl-bis (B-chloroethyl) amine hydrochloride obtained in the course of this study will appear later.

METHOD

Marrow cultures were set up as previously described,⁶ using sterile ascitic fluid as a source of protein instead of human cord serum. A marrow culture was prepared from each of 8 patients with miscellaneous diseases displaying essentially normal marrow pictures. In addition, the bloods of 4 patients with chronic granulocytic leukemia, 2 with acute lymphocytic leukemia, 1 with acute monocytic leukemia, and 1 with multiple myeloma with a plasmacytic-leukemia blood picture were cultured in the same way as marrow. Each culture was first thoroughly shaken in one vial and then equal parts were transferred to a series of vaccine vials, one of which was left as a control to which the solvent only was added and to the others equal volumes of varying concentrations of urethane or of methyl-bis (B-chloroethyl) amine hydrochloride in isotonic saline were added. Since no references were found giving the actual blood levels of urethane obtained in clinical therapy, a wide range of final concentrations was used, including 1:200, 1:1,000, 1:2,500, 1:5,000, 1:10,000, 1:20,000, and 1:40,000, although not all concentrations were used in each experiment. The morphologic data were based on the study of Wright's stained smears made at the same time from the control, urethane and nitrogen mustard cultures. The samples for the smears were removed three hours after the drugs were added and at approximately twenty-four hours.

From the Division of Experimental Medicine, University of Oregon Medical School. Aided by a grant from the Medical Research Foundation of Oregon.

intervals thereafter for five days. The criteria of cell identification and classification were those given and illustrated by Osgood and Ashworth.⁷

OBSERVATIONS

The morphologic changes in structure of the cells of the granulocyte series noted in the cultures containing urethane are illustrated in figure 1 and outlined in table 1.

The first change to appear was a 5 to 10-fold increase in the number of progranulocytes in process of mitotic division as compared to the control. This was noted as early as three hours and in concentrations as low as 1:40,000. The increase in mitoses was most marked at twenty-four hours and persisted for seventy-two hours. All phases of mitotic division were seen but most were normal appearing metaphases similar to those illustrated in figure 2 by Osgood.⁸

The most commonly observed change was the condensation of the basichromatin in the nucleus of the progranulocytes and granulocytes into dense blocks separated by clear spaces and still surrounded by a nuclear membrane as shown in figure 1-a. This appeared as early as three hours, steadily increased as long as the cultures were observed, and was most marked in the higher concentrations, although it was noted with all concentrations.

The alteration in morphology shown in figure 1-b was frequently observed in the progranulocyte and granulocyte stage. There seemed to be a loss of the nuclear membrane and imperfectly square or rectangular projections from a mass of clumped chromatin. A somewhat similar picture is seen in the anaphase of normal mitotic division when the cell is so oriented that the plane of cell division is parallel to the plane of the slide, but the number of these cells was greater than would be expected from the number of cells seen in the metaphase of division and it seems probable that at least some of the cells showing this appearance represent an intermediate stage of karyorrhexis between figure 1-a and figure 1-c.

The most striking but least frequently observed change is shown in figure 1-c. It consisted of the appearance within the cell of numerous fragments of densely-staining, structureless chromatin in round, ovoid or rectangular blocks with no nuclear membrane. This appearance was somewhat suggestive of the colchicine arrest of mitosis in the metaphase,⁹ illustrated in figure 1 in Osgood,¹⁰ but careful studies showed the points of difference outlined in table 2. It seems more probable, therefore, that the urethane effect illustrated in figure 1-c represents karyorrhexis or fragmentation of a nucleus similar to that in figure 1-a.

Double nuclei with no suggestion of fission of the cytoplasm were frequent in the progranulocyte and all subsequent stages of the granulocyte series in the urethane-containing cultures, yet the cells did not appear to be appreciably larger than the corresponding cell type with a single nucleus. They seemed to be most abundant in the granulocyte stage but appeared first in the progranulocyte stage as illustrated in figure 1-d.

Another change in morphology which is not illustrated was a marked decrease in size of some of the neutrophil lobocytes and rhabdocytes, both as compared to the control culture and to the average normal size of these cells. This change was even more noticeable in the blood of some of the patients treated with urethane over long periods of time.

FIG 1 Photomicrographs of cells of the granulocyte series from urethane-containing culture (a-d), and leukemic blood (e), Wright's stain $\times 1800$

- a Neutrophil granulocyte showing chromatin clumps within the nucleus
- b On the left is a cell which is either a neutrophil progranulocyte S in the anaphase of mitotic division viewed end-on or a neutrophil granulocyte showing an intermediate stage of karyorrhexis of the nucleus between figure 1-a and 1-c. On the right is a neutrophil rhabdocyte of perfectly normal morphology
- c Neutrophil granulocytes showing fragmentation or karyorrhexis of the nucleus into numerous deeply-staining round or ovoid blocks of varying size
- d Progranulocyte A with double nucleus
- e This is a progranulocyte A from the blood of a patient with chronic granulocytic leukemia under treatment with urethane in process of amitotic division showing the mode of formation of the double nuclei. Note the rectangular projections from the nucleus with rounded corners. Amitotic division and double nuclei are almost never noted in the granulocyte series in either normal blood or marrow or blood or marrow from patients with leukemia who are not receiving urethane. Note that there is no tendency toward fission of the cytoplasm.

In addition, many of the cells of the granulocyte series developed dense, pyknotic, structureless nuclei and showed signs of loss of the cell membrane and disintegration.

None of these changes was noted in significant numbers in cells of the lymphocyte, monocyte, or plasmacyte series cultured or in the granulocyte series in the control and nitrogen mustard cultures. They have rarely if ever been observed by the authors in the course of an extensive study of the blood and marrow of patients with granulocytic leukemia or other diseases when urethane was not being given.

In each of the cultures and with each of the concentrations of urethane employed, many of the cells at each stage of development showed none of these changes and

TABLE 1 — *Approximate Percentage of Progranulocytes and Granulocytes Showing Morphologic Changes*

Changes observed	Control cultures 1 to 5 days	Cultures containing urethane	
		1 day	5 days
Normal	Over 99%	90%	Less than 20%
Mitoses	Less than 1%	7%	Less than 1%
Chromatin blocks (Figure 1-a)	Not seen	Less than 1%	60-70%
Separate chromatin blocks (Figure 1-c)	Not seen	Not seen	Less than 1%
Double nuclei (Figure 1-d)	Not seen or less than 0.1%	Less than 1%	15%

TABLE 2 — *Effects on Morphology of Cells Produced by Colchicine and Urethane*

	Colchicine	Urethane
Chromatin blocks	rectangular or square uniform in size number = or > normal no. of chromosomes	round, ovoid or with rounded corners unequal in size number < normal no. of chromosomes
Mitosis	arrested in metaphase	initial stimulation goes on to completion
Amitosis	not affected	greatly increased
Differentiation	prevented in higher concentration (1:100,000)	markedly abnormal but occurs in 1:200
Cell size	giant forms common	dwarf forms common
Nuclei	enlarged	pyknotic

appeared indistinguishable in morphology from cells of the corresponding stage of development in the control cultures or in the original marrow or blood of the patient. Such a normal appearing cell is illustrated by the neutrophil rhabdocyte in figure 1-b.

All of the changes noted in the cultures were also noted in blood or marrow of patients receiving 1 gram of urethane three times daily. The cell in figure 1-e is from the blood of a patient receiving urethane therapy. It shows the formation of double nuclei, apparently by amitotic division.

COMMENT

The changes in morphology of the cells of the granulocyte series observed in blood and marrow cultures containing urethane suggest an effect of this drug on the state of aggregation or organization of the nucleoprotein within the cell nucleus, a tendency to disrupt the nuclear membrane and to interfere markedly with the normal process of cell division and cell growth. They resemble in many respects the changes described by Dustin,⁴ Burt,¹¹ Piton,¹² and Chodkowski¹³ and others whose work is cited in the references herein given,^{1,2,4,11-13} as produced by a wide variety of unrelated "karyoklastic poisons," including many urethanes, many narcotics and arsenical compounds which seem to act by altering the permeability and integrity of cell membranes and nuclear membranes and the state of colloid aggregation of the nuclear and cytoplasmic proteins.

The morphologic effects produced by urethane were not seen in marrow cultures exposed to nitrogen mustard. While some of the changes superficially resemble those produced by colchicine,^{5, 9-10} there are important differences. Colchicine, in adequate concentration, seems to arrest mitotic division completely, whereas urethane apparently stimulates division at first and the majority of cells complete division and differentiation.

In previous studies, using the marrow culture technic, of the action of ionizing radiation including 200 KV and 1,000 KV roentgen rays, neutron rays and radioactive phosphorus, it was shown^{5, 9, 14-16} that in the dosage employed in treatment of leukemias, each modality of ionizing radiation inhibited the onset of the next division, mitotic or amitotic, rather than actually killing cells. In none of these experiments were morphologic changes similar to those noted in the urethane cultures observed, nor was the initial increase in mitoses and in total cell count which occurred in the urethane cultures noted.

We have confirmed the clinical observations of Paterson and her co-workers² that there is a great difference in clinical response of patients with apparently identical forms of leukemia to similar doses of urethane. It so happened that bloods of 2 of these patients were selected for culture before urethane was administered. Both patients were middle-aged women with long-standing chronic granulocytic leukemia with typical blood pictures. Both had been treated until resistant with local x-ray and not with the preferred total body irradiation at regular intervals. Both had refused further x-ray treatment. Case 1, unit number 157378, who responded well to urethane, had had a splenectomy several years previously because of the huge size of the spleen. Case 2, unit number 157231, which failed to respond to urethane, had a huge spleen reaching to the left iliac fossa 25 cm below the costal margin and extending across the midline. In other respects, they were as nearly alike as any two cases of chronic granulocytic leukemia could be. Both were given 1 gram of urethane three times a day.

In case 1, the leukocyte count had dropped from 33,800 to 7,700 after thirteen days of therapy, totalling 36 grams, and to 2,000 by the eighteenth day of therapy, totalling 51 grams, at which time the therapy was discontinued. In the course of the next twelve days, the leukocyte count dropped to 600 and, although the urethane had been stopped, it continued at this low level for many weeks, during

which time stomatitis from the agranulocytosis was controlled with difficulty by penicillin therapy. She then had a gradual reversion to a more normal leukocyte count.

In case 2, the initial leukocyte count before therapy was oscillating between 50,000 and 90,000 and was still about 50,000 after 141 grams of urethane were given in the course of thirty-nine days. The differential cell count pattern was not significantly altered and the size of the spleen was unchanged. Both patients had a good deal of nausea and some vomiting from the drug, and it is possible that in case 2 some of the drug was lost in the vomitus or was not taken, so during the last of the course the dose was increased to 4 grams daily, still without effect. This patient subsequently showed an excellent response to intravenous radioactive phosphorus therapy as far as leukocyte count and alteration in spleen size were concerned, although requiring somewhat higher dosage than the average patient who had not had x-ray therapy previously.

In the cultures of these two bloods to which urethane was added, however, the morphologic changes observed were, within the experimental limits of the method, indistinguishable in character and percentage of cells involved, suggesting that the clinical differences in response were due to differences in concentration of the active compound actually reaching the cell.

SUMMARY

In cultures by the marrow culture technic of human marrow and leukemic blood containing concentrations of urethane from 1:200 to 1:40,000, marked changes in the morphology of the cells of the granulocyte series were noted.

These changes were not noted in the control nor in duplicate cultures containing the methyl-bis (B-chloroethyl) amine hydrochloride form of nitrogen mustard in concentrations from 1:500,000 to 1:40,000,000, nor were they noted in previous studies of cultures containing colchicine or exposed to 200 kilovolt or million volt x-rays, neutron rays or radioactive phosphorus, nor in the bloods or marrows of patients with untreated chronic granulocytic leukemia, of healthy individuals or of persons with miscellaneous diseases.

The changes consisted of an early increase in number of normal mitoses in the progranulocytes, a steadily rising percentage of granulocytes and progranulocytes showing condensation of the chromatin in the nucleus into dense fragments separated by clear spaces, a progressive increase in the number of cells of the granulocyte series with double nuclei, affecting all cells from the progranulocytes to the neutrophil lobocytes but appearing to be most numerous in the granulocyte stage, and the appearance in the cultures by 4 to 5 days of cells containing separated fragments of structureless material staining like basichromatin, which probably represents a karyorrhexis of the nucleus.

Note. Nothing in this article is to be construed as a recommendation of urethane for the clinical treatment of leukemias. While many years must elapse before its place in therapy can be evaluated, it does seem worthwhile to give urethane a trial for metastatic malignant tumors. Our present impression is that either radioactive

phosphorus or total body irradiation with x-rays given in small regularly spaced doses is far superior to urethane in the treatment of leukemias¹⁷ When the cells become resistant to radiation therapy, urethane may be worthy of a trial

ANTIBIOTICS IN CHRONIC LEUKEMIA

By DUDLEY MERRILL, M D

THE day by day care of patients with chronic leukemia of any type is one which will tax the ingenuity of the physician to the utmost. These patients can sometimes be carried along for several, if not many, years, in comparative comfort with X-ray therapy and transfusions as often as necessary to maintain a hemoglobin between twelve and thirteen grams. One of the characteristics of these patients is their liability to infections and their extremely poor resistance to them. In fact, infection is one of the common causes of death in this particular group.

Prior to the discovery of the sulfonamides, penicillin, streptomycin and tyrothricin, an attack of pneumonia, a cellulitis of the throat, or an infected hematoma often resulted in death in a few days from overwhelming sepsis. This was true even in patients whose general condition was such prior to the infection that many weeks or months of active life could have been anticipated in spite of the leukemia.

For many years, it was seriously questioned by many authors whether X-ray therapy actually prolonged life in patients with chronic leukemia. It is practically impossible to prove this proposition statistically because of the extreme variation of life expectancy in these patients without any treatment whatever. When life expectancy ranges from six months to twelve years, an average or a mean becomes a mathematical figure of little or no significance when applied to an individual case.

The same is true of any attempt to evaluate in a statistical fashion the effect of antibiotics, nitrogen mustards, urethane or Fowler's solution on the course of leukemia.

The extraordinary value of the antibiotics in the management of infections in general has now been conclusively established. These drugs have also revolutionized many of our long accepted medical and surgical beliefs as well as many of our apparently well established rules of prognosis.

The care, as well as the prognosis, of patients with pneumonia, meningococcus meningitis, spreading streptococcal infection, osteomyelitis and bacterial endocarditis, have been profoundly altered in the past ten years.

One of the most revolutionary technics for the handling of mild or severe cellulitis and lymphangitis localized or spreading, including even the face and nose, has been the injection of penicillin in large doses directly into and around the infected tissues. Rose and Hurwitz¹ have demonstrated the complete safety and great usefulness of this method. The superiority of this approach over parenterally administered penicillin at a distant site is not surprising when one considers the immense concentrations of penicillin achieved at the site where it is most needed. Comparable concentrations from penicillin injected at a distance from the infection, either intramuscularly or intravenously, obviously would necessitate massive doses. The simplicity and inexpensiveness of the procedure are also in its favor.

Luckily, none of the effectiveness of the antibiotics depends upon the integrity

From the Mt. Auburn Hospital, Cambridge, Massachusetts

of the leukocytes. Thus, they are equally efficacious in coping with infection in patients with profound disorders of the white blood cells such as agranulocytosis, aplastic anemia, or any form of leukemia. Two cases* are presented to illustrate

CASE REPORTS

Case No. 1 J. J. This 15 year old boy was diagnosed as having leukemia after having been 'run down' for about four months. His blood count showed Hgb 34 per cent (S), RBC 1.69, and WBC 25,600. The smear showed 60 per cent large immature white cells. These were classified as either immature monocytes or histiocytes by a consulting hematologist. Treatment was decided upon in spite of the obviously poor prognosis. He was repeatedly transfused and given small doses of x-ray therapy with rapid symptomatic improvement.

About a month after treatment was started, he developed a painful hematoma in his right calf and smaller ones in the sole of his left foot and in his left cheek. In the next week his temperature rose gradually to 105 F in spite of full doses of sulfadiazine by mouth. The hematoma of his leg increased in size, induration, redness, and painfulness, until it occupied an area 15 x 10 cm. It finally broke down and discharged vast quantities of serosanguineous material. Coping with such a large ulcer which oozed such enormous quantities of serum, blood, and pus, and was extremely painful when dressings were changed, was finally solved by Doctor Robert Linton, who placed the leg in a cast and packed the ulcer with gauze impregnated with tyrothricin ointment. There was a dramatic improvement in the boy's general condition, with a drop of his temperature to normal. In three days' time, he was able to be up in a wheel chair. When the cast was changed after thirteen days, the ulcers were filling in rapidly. Eighteen days later, he was allowed home, where he was comfortable getting about in a wheel chair for the next month except for one brief return to the hospital for further transfusions. Finally, however, he had a recurrence of multiple hematomas, his white count rose to 190,000 with 98 per cent extremely immature cells, and he went downhill fairly rapidly in spite of x-ray therapy, transfusions, and tyrothricin applications to his ulcerated hematomas. He died approximately five months after the diagnosis was established and eight months after his first symptoms.

Postmortem examination established the diagnosis of monocytic leukemia.

Case No. 2 Mrs. M. M. This 74 year old woman was first seen because of anemia. She had a Hgb 46 per cent (S), RBC 1.90, WBC 3,250. The differential showed P 44, L 32, M 24, and 2 nucleated RBC/100 WBC. The platelets were normal, the RBC deeply stained, and there were many tailed cells. It was felt that her blood picture was consistent with pernicious anemia.

After one month on liver extract, 15 units intramuscularly once a week, her Hgb was 35 per cent (S), RBC 1.55, and WBC 4,500.

A sternal biopsy was then done and reported by Doctor H. E. MacMahon as follows: 'The overall picture is one of aplastic anemia, but there are tiny foci showing a picture consistent with pernicious anemia under treatment.'

Large doses of folic acid, liver extract powder, and intramuscular liver extract were given, but there was no response whatever. The patient was kept in excellent health without any complaints for a whole year by repeated blood transfusions.

Then increasing numbers of abnormal white cells began to appear, coincident with the development of areas of cellulitis on both sides of her neck and in both nostrils. The next day, penicillin, 25,000 units every three hours intramuscularly, was started, but in two days' time the cellulitis had spread and now involved the lower lip and cheek which were enormously swollen. She was then given 50,000 units of penicillin in 5 cc of saline directly into the infected areas. There was rapid improvement with resolution of the areas of cellulitis without any breaking down of the tissues. Parenteral penicillin was stopped nine days after the local injection had been given.

Six days later, however, a new area of cellulitis on the left side of the lower lip had appeared and paren-

* Both of these cases are reported through the courtesy of Dr. Arthur N. McKechnie of Cambridge, Mass.

teral penicillin every three hours was again started. Five days later, this was changed to single daily injections of 300,000 units of penicillin in peanut oil and beeswax because of breaking down and abscess formation in the areas previously injected with penicillin in saline.

On this treatment, the areas of cellulitis about the lips and mouth subsided but she developed many new areas about the chin, cheeks, neck, right upper arm, and both buttocks. Her white count rose to 64,600 with more than 50 per cent extremely immature forms.

All therapy was finally abandoned, and the patient died about ten weeks after the first appearance of the areas of cellulitis in her neck. She had received a total of 19,575 cc. of whole blood in the course of fourteen months, and for twelve of those months she had had extraordinarily few, if any complaints.

Autopsy showed monocytic leukemia and extensive hemosiderosis of liver, spleen, lymph nodes, and bone marrow, consistent with hemochromatosis. This latter finding was presumably due to her enormous number of transfusions.

CONCLUSION

The new antibiotic drugs, sulfonamides, penicillin, streptomycin, and tyrothricin, have proved useful in the management of the infectious complications in leukemia and other disorders of the bone marrow.

FOLLICULAR LYMPHOBLASTOMA

A REPORT OF SIX CASES

By OVID O MEYER, M D

FOLLICULAR lymphoblastoma has been a subject of considerable interest since 1925 when Brill, Baehr, and Rosenthal¹ reported the 2 cases which made the medical profession really cognizant of this entity. They called the condition generalized giant lymph follicle hyperplasia of lymph nodes and spleen. Much earlier, in 1901, Becker² had described a case which probably was this disease, and between 1912 and 1920 descriptions³⁻⁵ of a few additional cases were reported. In their original report Brill, Baehr, and Rosenthal¹ concluded that the lymph node disease was probably benign, but in a subsequent report published two years later Baehr and Rosenthal⁶ concluded on the basis of six cases studied, that the condition was malignant. In the same year, however, Symmers⁷ described 3 cases on the basis of which he concluded that the condition was benign from the "standpoint of prognosis." In an extensive report published in 1938, Symmers⁸ described, with the histologic picture, cases of giant follicle hyperplasia which later were transformed into polymorphous cell sarcoma of the lymph follicles, others which appeared to terminate as Hodgkin's disease, and still others which ended as "lymphatic" leukemia. He stated that giant follicular lymphadenopathy, with or without splenomegaly, was probably inflammatory or toxic in origin and usually amenable to mild roentgen therapy. In a communication published in 1946,⁹ he stated that he had seen 5 histologically proved cases in which roentgen therapy was followed by apparent cures for periods of 3, 4½, 5, 9½, and 12 years. Another patient survived nine years without any treatment. Baggenstoss and Heck,¹⁰ on the other hand, agree with the conclusion which Baehr, Klemperer, and Rosenthal¹¹ had arrived at by 1931, namely that the disease is a form of lymphosarcoma which in its early stages presents the histologic picture of follicular hyperplasia but is later characterized by a conglomeration of the follicles and diffuse infiltration of the lymph nodes by polymorphous lymphoblasts. It was at this time that the term "follicular lymphoblastoma" was proposed.¹¹ By 1940, Baggenstoss and Heck¹⁰ had collected 59 cases from the literature and 13 of their own, a total of 72. In 1941, Gall, Morrison, and Scott¹² reviewed 63 cases from biopsy or necropsy material submitted to the laboratory of the Massachusetts General Hospital. Since publication of this report, more than 50 additional cases¹³⁻³⁹ have been recorded through 1946. These include 15 cases with skin manifestations reported by Combes and Bluefarb.³⁰ The present paper reports 6 additional cases.

The chief characteristics of follicular lymphoblastoma are outlined by Baehr, Klemperer, and Rosenthal.¹¹ Enlargement of the lymph nodes is due to enormously enlarged lymph follicles, a single one of which may fill a low power microscopic field. The follicles resemble huge germinal centers consisting of lymphoblasts with

From the Department of Medicine, University of Wisconsin Medical School.

frequent mitotic figures. The periphery of each large follicle is surrounded by a narrow zone of small lymphocytes whose nuclei stain darker. The splenomegaly may be enormous as a result, chiefly, of enlargement of Malpighian bodies. There are no abnormal cells in the blood. Nor is anemia and cachexia present until the end stages of the disease. There is a tendency to lymphatic infiltration in the lacrimal gland, which gives rise to unilateral exophthalmus, and there is a tendency to involvement of serous membrane with pleural or peritoneal serous or even chylous effusion. The disease is remarkable for its chronicity and its extreme radiosensitivity. No neoplastic disease responds more promptly to relatively small doses of roentgen or radium therapy. Recurrences in widely separated parts of the body usually take place after varying intervals until eventually, often after many years, there is radioresistance.

The present report is of 6 cases seen at the State of Wisconsin General Hospital since 1941. Two, cases 2 and 6, were of particular interest because of bone involvement. Three of the patients were women, 3 were men. The ages were 54, 45, 44, 61, 82, and 60 respectively.

CASE REPORTS

Case 1. L M M, age 54, a white farm housewife, was admitted September 3, 1941. She complained that for six months she had been afflicted with shortness of breath and a cough. In the spring of 1941, she noted a painless swelling of the right side of the neck. She saw a physician on July 3 and was hospitalized. A left pleural effusion was demonstrated, and thoracentesis was performed on three occasions, each of which was followed by temporary relief of dyspnea.

Examination showed an obese white woman, able to sit up in bed. The trachea was deviated to the right. There were 2 cm. nodes in the right cervical region, several 1 cm. nodes in the left posterior cervical chain, and a healed surgical scar of biopsy on the right. The nodes were freely movable, nontender, and without induration. No other enlargement of lymph nodes was demonstrated. There were signs of a massive fluid accumulation in the left thorax. The blood pressure was 170/90. The liver extended 3 cm., the spleen 8 cm. below the costal margin.

Laboratory studies showed a hemoglobin of 14.5 Gm. (90 per cent), erythrocytes 3,930,000, leukocytes 5,500, neutrophils 64, lymphocytes 32 per cent, monocytes 2, eosinophiles 2 per cent. Blood Wassermann was negative. A roentgenogram of the chest as read by Dr. L. W. Paul showed massive left-sided opacity, presumably due to pleural effusion. Bucky film after aspiration of fluid did not demonstrate enlargement of mediastinal nodes. The tuberculin test was negative.

Thoracentesis on three successive days resulted in the withdrawal of 1500 cc. of chylous fluid on each occasion. No organisms were found in the fluid, and it was negative for acid-fast bacilli. The specific gravity was 1.023, and albumen 2 per cent, there were many red blood cells. Biopsy of a node from the right cervical region on September 6, 1941, showed the findings of follicular lymphoblastoma.

The patient received eight treatments of 150-r to 200-r each in air (H V L = 1.05 mm. distance 50 cm.) between September 8 and 13, 1941, and she went home. In October she returned to the outpatient department. Earlier in the month she had required a thoracentesis. There had been no gain in weight, but she felt better. Her cough, however, and the signs of a small fluid accumulation in the left pleural cavity persisted. There were no palpable lymph nodes, the spleen was about 6 cm. below the costal margin. On January 8, 1942, the patient reported a ravenous appetite, an 8 pound gain in weight, and for three weeks recurrent backache in the mid-lumbar region which was severe enough to cause much loss of sleep. The cough had disappeared. Examination showed tiny cervical and axillary nodes. The spleen was 2-3 cm. below the costal margin. There was muscle spasm and tenderness in the right lumbar region. A roentgenogram of the lumbar spine was negative for bone or joint disease. Three treatments of 150-r each were given to the spine. Subsequently, after the patient had returned home, massage and diathermy were administered, since the pain persisted.

She was readmitted to the hospital on April 27, 1942, suffering torturing pain in the back and down into the legs. She had increasing difficulty in walking and loss of control of the bladder and bowels.

Physical examination at this time revealed signs of a moderate accumulation of fluid in the left pleural cavity, the spleen was just palpable, and there was no enlargement of the lymph nodes. The patient could no longer move the lower extremities, the deep reflexes had ceased, and the vibratory sense and position sense were absent. There appeared to be deformity of the 8th thoracic vertebra.

FIG. 1. SECTION OF A CERVICAL LYMPH NODE OF PATIENT L. M. M., CASE NO. 1.
MAGNIFICATION 30X.

Laboratory studies showed the hemoglobin to be 11.4 Gm (70 per cent), leukocytes 4,500 with 76 per cent neutrophils. A roentgenogram of the dorsal and lumbar spine showed no definite bone lesions.

It was believed that the patient had a lesion compressing the cord, and five treatments totaling 1100-r in air (H.V.L. = 1.05 mm, distance 50 cm) were administered to the dorsal and lumbar regions. She returned to the hospital for the last time on July 9, 1942. Her condition has not improved, ten days before, her legs had become slightly flexed at the hips and knees and it was almost impossible to move them.

There was anesthesia in both legs, due to apparent sacral segment lesion, and in the right leg it extended to lumbar 4. Deep reflexes were absent. Roentgenograms of the dorsal and lumbar spine were negative. The laboratory studies were not significantly different from those made in April. Six treatments of 200-r each in air (H.V.L. = 2.4 mm, distance 60 cm) were administered to the dorsal and lumbar spine between July 1 and 7, 1942, and the patient was discharged. She died at home about two months later and autopsy was not obtained.

Comment Involvement of the pleura with effusion was prominent in this patient. The unproved but apparent involvement of the spinal cord was unusual. The course was rapid, death occurring within 18 months of onset of the lymph node enlargement.

Case 2 C A J, age 45, an American housewife of Dutch descent, was admitted on May 13, 1946, complaining of pain in the left leg. Her illness had begun three years before with episodes of gaseous distension, nausea, and diarrhea. Several months later she noted enlargement of nodes in the inguinal regions, enlargement of the abdomen, and then the presence of lumps in the neck and axillae. Biopsy was made and x-ray therapy given. The nodes disappeared. A few months later she complained of pains in the arms, legs, and lower abdomen. These gradually decreased without specific therapy. After this she had been able to do hard work until two months before admission when she again suffered pain in the left leg and lower back.

Physical examination showed a well-developed, well-nourished, though pallid woman. The largest of a few palpable nodes, 2 cm in diameter, was in the right axilla. The liver and spleen were not palpable.

Laboratory studies showed 4 plus glucose in the urine, hemoglobin 11 Gm (70 per cent), erythrocytes 3,415,000, leukocytes 2,700 with neutrophils 69, eosinophils 0.6, small lymphocytes 7, atypical lymphocytes 2.6, intermediate and large lymphocytes 3.4, young lymphocytes 5, monocytes 11.4, metamyelocytes 0.8, neutrophilic myelocytes 0.2 per cent. Reticulocytes numbered 1.4 per cent. The volume of the individual cell was 94.2 cu microns. A roentgenogram of the chest showed no enlargement of mediastinal nodes. The roentgenogram of the pelvis as read by Dr. L. W. Paul showed areas of increased density in the ischial rami, particularly on the left side, with a suggestion of a little mottling in the upper ends of the femurs. These changes were thought by Dr. Paul to be consistent with early involvement of these bones by a lymphoblastoma.

Biopsy of an axillary lymph node was performed, the description of Dr. Walter Jaeschke being as follows. This moderately enlarged node has a moist grey medullary appearance on cut section. Throughout, there are giant follicles separated by a lymphoid stroma. In the stroma, there are numerous eosinophils. Reed-Sternberg cells are not identified. Diagnosis: giant follicle lymphoblastoma.

The patient received 600-r in air of high voltage roentgen therapy (H V L cu = 1.05 mm distance 50 cm) to the right and left axilla and a similar dosage to the anterior and posterior pelvis. She was discharged on May 22, 1946. Her local physician reports that the patient died in July, 1946.

Comment This patient, who had symptoms for three years before coming under our observation, had definite anemia by this time. There is in the literature little to suggest involvement of bone with follicular lymphoblastoma, but since it is common in other types of lymphoblastoma, its occurrence in 2 of the 6 cases here described is probably not surprising.

Case 3 E R H, a 44-year-old white male, was first admitted to the Wisconsin General Hospital on April 28, 1942, complaining chiefly of lumps on the head and left side of the neck. He had had an enlarged node behind the right ear as long as he could remember. About nine months before admission, he had first noted three small lumps on the right side of the head. These slowly increased in size, and a week before admission another lump appeared on the left side of the head. A biopsy of a node from the scalp showed hyperplastic follicles. He had lost 22 pounds in weight.

Physical examination showed this patient to be a well-developed, well-nourished man of good color. On the right side of the head were three firm, but movable, masses measuring 2 x 3 to 2 x 4 cm. On the left side, also in the region of the scalp was a single smaller node, and in the left submaxillary region was a firm node measuring 3 x 5 cm. In the neck were several smaller nodes and there were also small nodes in the right postauricular, the axillary, epitrochlear, and inguinal regions. Blood pressure was 200 systolic, 120 diastolic. The liver extended 3 cm, the spleen 2 cm below the costal margin on deep inspiration.

Laboratory studies showed a hemoglobin of 15.9 Gm (100 per cent), erythrocytes 4,280,000, leukocytes 8,600 with neutrophils 76 per cent, lymphocytes 23 per cent, eosinophils 1 per cent. Blood

Wassermann was negative. The basal metabolic rate was plus 37. Roentgenograms of the chest showed cardiac enlargement. X-ray of the skull was negative. Biopsy of the node in the left submandibular region was interpreted by Dr. W. D. Stovall as giant folliculoma (follicular lymphoblastoma).

FIG. 2. SECTION OF AN AXILLARY LYMPH NODE, CASE NO. 2. MAGNIFICATION 60X.

The patient was discharged on May 5, 1942, to report to the outpatient department for roentgen therapy. He has been seen repeatedly in the outpatient department and has twice been readmitted to the hospital, in May, 1943, and on January 11, 1945, at which time he complained of dyspnea, orthopnea, precordial pain, and cardiac arrhythmia. For five months he had been hoarse and for a week had noted enlargement of the spleen with pain in this region. The right side of the neck was swollen.

The patient was apprehensive. There was general superficial enlargement of the lymph nodes, several small nodules scattered in the subcutaneous tissue, signs of bilateral intrapleural fluid. The liver extended 6-8 cm below the costal margin, and the spleen was palpated 16 cm below the costal margin. The blood pressure was 185 systolic, 120 diastolic.

Laboratory studies included a urinalysis with 5 to 10 casts per low-power field, specific gravity 1.026. The blood count was still essentially normal. A roentgenogram of the abdomen showed enlargement of the spleen and liver. An x-ray of the chest showed the presence of fluid bilaterally. There was also moderate enlargement of the mediastinal nodes.

It was thought that much of the symptomatology and the pleural effusion were attributable to the cardiac disease rather than to the lymphoblastoma. However, the patient received 12 treatments of 150-r each in air (H V L cu = 1.05 mm distance 50 cm) distributed to the spleen, right cervical, and mediastinal regions. He was discharged January 25, 1945. On April 15 of that year, his physician reports the patient died of cardiovascular renal syndrome.

Comment The duration of this case of lymphoblastoma could not be ascertained but seemingly it was long if the original "lumps" are significant. If not, then the course was short, death resulting from the cardiac and renal failure induced by the severe and persistent hypertension. Pleural effusion is common in follicular lymphoblastoma, but here it was thought to be cardiac rather than lymphomatous in origin.

Case 4 Mrs. J. H., age 61, the wife of a missionary to China for many years, visited the outpatient department on March 5, 1946, with the complaint of a lump in the right groin. Sixteen years before, while in China, her left eye had been removed for what was found to be a malignant tumor of unknown type. On July 24, 1941, 32 cm of rectum and sigmoid were removed and a colostomy performed for a neoplasm which was localized and found to be an adenocarcinoma. On May 17, 1943, a tumor in the left inguinal region was removed. A microscopic study of this lymph node showed greatly enlarged lymph follicles with some confluence. The individual cells making up these follicles possessed a curious pleomorphism. They invaded the capsule and the surrounding fat. The diagnosis was "malignant lymphoblastoma." A preauricular lymph node which had become enlarged in 1943 disappeared completely following high voltage roentgen therapy. Late in February, 1945, a growth on the hard palate was resected. Sections showed fibrous tissue moderately infiltrated with lymphocytes, a few plasma cells, eosinophiles, and occasional polynuclear neutrophils. There were no Reed-Sternberg cells. The interpretation was chronic granulomatous inflammation. On April 3, 1945, a tumor was removed from the region of the right scalenus muscle, sections as studied by Dr. S. B. Pessin showed a distorted lymph gland with the normal architecture completely destroyed. The predominant cells were large and medium-sized lymphocytes, containing a vesicular nucleus with one or two distinct nucleoli. There was a small amount of fibrosis in some areas and considerable delicate reticulum. Occasional mitotic figures were seen. The diagnosis was reticulum cell lymphosarcoma.

Early in November, 1945, the patient noted a lump in the right groin which brought her to the State of Wisconsin General Hospital on March 6, 1946. Eight days later, the node from the right groin was removed and at the same time a 3 cm node from the thyroid was excised. General examination at this time showed no other lymph node enlargement nor enlargement of the spleen and liver. There was no anemia, the total leukocyte count was 4,300 with a normal differential count. The section from the thyroid showed closely spaced giant follicles, but some fusion of follicles had taken place so that the picture resembled a fully developed reticulum cell lymphosarcoma. The diagnosis of Dr. Walter Jaeschke was follicular lymphoblastoma.

The patient has remained well to date and her case has been followed in the outpatient department.

Comment This is a rather amazing case with the evidence, quite reasonably substantiated, of multiple malignancies. The reports of the several lymph-node studies might well leave one confused, and perhaps the pathological findings were

not the same in the original studies as in the last.* This emphasizes, it seems, the close relationship between follicular lymphoblastoma and other malignant disease (lymphosarcoma). The last biopsy was sufficiently characteristic to justify the inclusion of the case in this series.

Case 5 J G This patient, a white male of 82, was admitted to the State of Wisconsin General Hospital on April 24, 1945. He had an enlarged right tonsil, which had first been noticeable four months before and had been progressively growing. There was no pain nor bleeding, and although the patient was conscious of the mass, it caused no real difficulty in eating.

The patient was very deaf and almost blind. The teeth were very carious. The enlarged right tonsil protruded well into the midline and filled half the throat. The mass was irregular, hard, and nontender. There was no enlargement of the lymph nodes, nor of the spleen and liver.

The blood count showed a hemoglobin of 11.6 Gm (70 per cent), erythrocytes 3,600,000, the leucocyte count was normal. A roentgenogram of the chest showed no enlargement of mediastinal nodes.

The tonsils were removed surgically. The left was fibrous. The right tonsil was 4 x 2.5 x 2 cm. There was loss of usual architecture, although a number of large giant follicles could faintly be made out. Throughout the sections there were occasional endothelial cells, numerous small round cells closely resembling lymphocytes, and occasional mitotic figures. The interpretation of Dr. W. D. Stovall was follicular lymphoblastoma. The patient died of bronchopneumonia six days after the operation. Post-mortem examination was not permitted.

Comment The disease in this instance involved, so far as could be determined, only the tonsil. Baehr, Klemperer, and Rosenthal¹¹ observed that in their cases the tonsils and lymphatic apparatus of the gastrointestinal tract had not been involved. Baggenstoss and Heck¹⁰ report 2 cases with tonsillar involvement and two other reports describe nasopharyngeal tumors with the histologic picture of follicular lymphoblastoma in which neither the lymph nodes nor spleen^{17, 20} were grossly involved. Tonsillar involvement with other types of lymphosarcoma is by no means rare.

Case 6 S W, a male Chippewa Indian 60 years old, was admitted to the Wisconsin General Hospital on April 29, 1943, complaining chiefly of weakness. He had been in good health until six weeks previously, when he began to suffer from weakness which became progressive. Four weeks before admission, he had gone to his local doctor, and a week later he noted swelling of the penis and scrotum which progressed. Three days before admission he developed swelling of the left leg. In response to questioning he revealed that for two years he had noted enlarged nodes in the left inguinal region and similar nodes on the right for four or five months. During the past six weeks, nodes in the axillary and cervical region and an abdominal mass became apparent. There had been a nonproductive cough, and for seven weeks intermittent tarry stools. The patient had had pleurisy at the age of 21.

Physical examination showed a moderately well-nourished man. Scattered in the cervical, supraclavicular, and axillary regions were moderately firm, discrete nodes 1 to 2 cm in size, and there was a tiny left epitrochlear node. There were similar nodes, 2 to 3 cm in diameter, in the inguinal regions, and a large firm mass filled most of the left side of the abdomen. Expansion of the left lung was limited, and there was dullness at the left base. The liver and spleen were not palpable. The penis, scrotum, left lower extremity to the mid-thigh, and the right foot were moderately edematous.

Laboratory studies showed a hemoglobin of 13.3 Gm (80 per cent), erythrocytes 4,250,000, leukocytes 6,700 with neutrophils 64 per cent, lymphocytes 29 per cent, monocytes 2 per cent, and eosinophiles 5 per cent. Blood Wassermann was negative, Hanger's cephalin-cholesterol flocculation test was negative. Roentgenogram of the chest showed atelectasis at the left apex with displacement of the trachea to the left. There was extensive fibrosis and some calcification of the pleura with a small left pleural effusion.

* The biopsy section of April 3, 1945, has been reviewed and the diagnosis of reticulum cell lymphosarcoma confirmed.

The mediastinal shadow was widened, and radiating areas of infiltration extended into the field of the lower left lung. X-ray of the colon following barium enema showed marked narrowing of the sigmoid apparently due to an extrinsic mass. Gastrointestinal roentgenograms showed that the esophagus deviated sharply to the left in its upper portion and that the trachea was displaced in consequence of the fibrotic and calcified pleura of the left apex. The stomach was displaced upward because of abdominal masses and fluid. The duodenal loop was large and rounded, probably as a result of a mass of nodes about the head of the pancreas. Biopsies were done of an inguinal node, of an epitrochlear node, and later of an axillary node. Large hyperplastic follicles were noted, which almost crowded out the pulp lymphocytes. Dr. W. D. Stovall interpreted these nodes as malignant giant folliculoma (follicular lymphoblastoma).

The patient, after a period of twenty essentially afebrile days in the hospital during which time he received eight treatments of 200-r each of roentgen therapy ($HVL_{Cu} = 2.4 \text{ mm}$, distance 50 cm) to the anterior and posterior mid-abdomen, was discharged on May 19. He had been seen in the hospital and in the outpatient department at intervals of about three months to December 11, 1946, his hospital admissions totaling ten. He had continued to have quite general enlargement of the lymph nodes, and on his second admission the spleen and liver were enlarged. At times superficial nodes were as great as 5 to 6 cm in diameter. Roentgen therapy to various sites had been given with each admission. On several occasions, abdominal paracentesis, resulting in the removal of as much as 3,000 cc of creamy, foul smelling fluid, was done. Temporary improvement followed each course of therapy. In August, 1945, when he was admitted for the seventh time, he complained of having suffered shooting pains in the legs for ten days, making it impossible to walk. For four days previously, he had walked dragging his feet. He could move his toes slightly. Examination at this time showed scattered superficial nodes 1.5 to 3 cm in diameter, persistence of pulmonary changes, and marked weakness of the legs, though he could move them a little in bed. The knee jerks were present, but Achilles reflexes and abdominal reflexes were absent. Babinski and confirmatory signs were present bilaterally. There was tenderness over the spine at the level of the sixth and seventh dorsal vertebrae. Spinal tap was done and there was evidence of block.

Laboratory studies showed a hemoglobin of 10.7 Gm (69 per cent), erythrocytes 3,030,000, lymphocytes 4,240 with a relative lymphocytosis. Spinal fluid showed a negative serology, gold sol 001233 2100, no cells, sugar 63 mg, protein 415 mg per 100 cc of blood. X-ray of the spine showed no alteration in the vertebra, but roentgenogram of the chest showed distinct increase in the mediastinal mass with metastatic nodules in the right pleura. The patient received four roentgenographic treatments of 200-r each to the anterior and posterior mediastinum and was discharged as improved. He gradually regained some strength in his legs but in October, 1945, was still unable to walk. On this admission the hemoglobin was 8.2 Gm (50 per cent), erythrocytes 2,350,000. The chest x-ray showed a marked decrease in the width of the mediastinal mass but an increase in the size and number of the metastatic nodules on the field of the right lung. Further roentgenotherapy was administered to the mediastinum.

The patient was next admitted on August 1, 1946, complaining of pain and weakness about the right knee and in the right leg which was relieved by rest. He was thin and pallid. There were scattered enlarged lymph nodes 2 to 4 cm in diameter. There was a 2 x 2 cm tender nodule on the medial side of the right femur just about the knee. Roentgenogram of the right femur at the junction of the middle and lower thirds showed an osteolytic lesion involving the shaft of the femur for a distance of 7 to 10 cm. A large central rarefaction extended almost through the cortex laterally, and there were a number of smaller rarefactions which were intercommunicating. Pathologic fracture was thought to be imminent. The patient was placed in a hip spica cast and seven treatments of 150-r each in air ($HVL_{Cu} = 1.05 \text{ mm}$ to 2.40 mm, distance 50 cm) were administered to the femur through a window in the cast. As the right testis was enlarged, irregular, and hard, and was believed to be involved by tumor, a small amount of therapy was directed to it, also.

The patient next entered the hospital on November 26, 1947. The pain in the right lower extremity persisted but was less severe and less constant. The patient was thin and pallid. A few superficial nodes were palpable. There was tenderness of the left fifth rib. The cast was still in place on the right lower extremity. Hemoglobin at this time was 11.3 Gm (70 per cent), erythrocytes 4,320,000, leukocyte count 2,650 with 56 per cent neutrophils and 8 per cent eosinophils. The basal metabolic rate was plus 13 and plus 15. Serum proteins were albumin 4.9 Gm and globulin 2.1 Gm per 100 cc. Roentgenogram of the chest showed no evidence of recurrence of the mediastinal mass. X-ray of the right femur showed increased destruction of the cortex in the distal portion of the femur. Biopsy of a right epitrochlear node

which was made on December 3 showed the outlines of giant follicles (three and a half years after the inguinal biopsy) which were interpreted by Dr Walter Jaeschke as follicular lymphoblastoma. After five treatments of 200-r each in air (H V L $\text{cu} = 2.4 \text{ mm}$, distance 50 cm) to the femur through a window in the cast, the patient was discharged. The last admission was April 17, 1947. The patient at this time was emaciated. Biopsy of the bone lesion showed several small cellular foci composed of closely packed

FIG. 3. LATERAL AND A. P. VIEWS OF THE FEMUR, CASE NO. 6

small cells, apparently lymphocytes. There were no follicles. The interpretation of Dr. Walter Jaeschke was necrotic lymphoid tissue.

The patient died April 25, 1947. The autopsy was done by Dr. John W. Harman of the Department of Pathology, and he reported that the autopsy demonstrated a large, firm, diffuse, greyish-white retroperitoneal mass which included both adrenal glands, infiltrated the pancreas, was attached to the undersurface of the liver and surrounded and constricted the pelvi-ureteric junction of the left kidney. There were several discrete nodules of similar tissue in the liver (see fig. 4). The only enlarged lymph nodes seen were the left epitrochlear and right external iliac. The spleen weighed 250 Gm. Microscopically the

retroperitoneal mass, liver nodules, and enlarged lymph nodes had a predominantly follicular structure. The large follicles were widely separated by diffuse areas of small lymphocytes and were composed of similar cells themselves. By reticular stain the follicular structure was accentuated, each follicle was surrounded by a zone of compressed reticulin fibers. In all sections the cell type was almost exclusively

FIG. 4. SECTION OF THE LIVER SHOWING NODULES FROM THE AUTOPSY, CASE NO. 6

small lymphocytic, only rare clasmotocytes were seen. The splenic structure was normal, the follicles were few, small, and widely separated by the pulp. Diagnosis: malignant follicular lymphoma.

Comment. A male Indian with follicular lymphoblastoma which may have begun in 1941 and was diagnosed in 1943, evidencing widespread disease with probable involvement of the spinal cord and definite involvement of bone with resultant destruction. The architecture of the lymph nodes had changed, but some char-

acteristics of follicular lymphoblastoma persisted in the biopsy done in December, 1946, although the patient's condition was poor and the disease far advanced. The development of a bone disease such as this strongly suggests that we are dealing with a malignant tumor such as a lymphosarcoma. Finally, at autopsy, four years after onset of the illness, there was still the characteristic pathologic change of the follicular lymphoblastoma.

DISCUSSION

The six cases herein described represent varying symptomatic states dependent upon varying sites of the lesions and emphasize the protean manifestation of follicular lymphoblastoma. Two cases, No. 5 and No. 6, present previously rarely reported or unrecorded lesions.

Analysis of these cases tends to confirm observations made by Baehr, Klemperer, and Rosenthal¹¹ and by Baggenstoss and Heck.¹⁰ The disease tends to, but does not invariably, pursue a relatively slow course. The onset is ordinarily insidious. Pleural effusion was prominent, occurring in 3 of the 6 cases. Ascites was demonstrated in case No. 6. Hypochromic anemia was almost invariably present, when the patient was seen late, rarely so if seen early. The leukocyte counts showed nothing characteristic early or late. Cachexia was unusual until late in the disease. This is quite characteristic of other types of lymphosarcoma, however, whereas anemia appears relatively early in Hodgkin's disease. The course in those of our cases followed for long periods certainly suggests that one is dealing with a neoplastic process, malignant in character. Bone destruction, prominent in one case, No. 6, and involvement present in another, No. 2, further suggests the malignant character of follicular lymphoblastoma. In a word, our observations, although not extensive, tend to confirm the conclusion of Baehr, Klemperer, and Rosenthal¹¹ and Baggenstoss and Heck¹⁰ that this is a form of lymphosarcoma, and that, although readily amenable to roentgen therapy it is not ordinarily curable by this type of therapy, as has been suggested.³¹

This series does not enable one to form an opinion as to the duration of the disease, but general opinion holds that the course is slower than with the other forms of lymphosarcoma. Of our cases, No. 6 has been ill for four years and may have had lymph node involvement for six years. Case No. 1, whom we observed from early in her course to almost the end, survived about eighteen months. Baggenstoss and Heck¹⁰ have discussed well the pathologic differentiation of follicular lymphoblastoma and lymph node hyperplasia of inflammation and our observations add nothing in this regard. Evans³² has listed the pathologic differences of lymphadenitis of secondary syphilis and follicular lymphoblastoma.

CONCLUSIONS

Six cases of follicular lymphoblastoma are here reported. They demonstrate a variety of pathologic lesions with a characteristic histologic picture with variable symptoms and signs. Tonsillar involvement was unique as the sole demonstrable lesion in one. Bone involvement occurred in two.

Study of these 6 cases leads us to believe that we are dealing with a clinical and pathologic entity and a malignant tumor, one which is usually highly sensitive to roentgen therapy, but ordinarily recurrent and progressive

THE SIGNIFICANCE OF MEGAKARYOCYTES IN THE PERIPHERAL CIRCULATION

By SIR LIONEL WHITBY

SOME of George Minot's earliest publications were concerned with platelets and megakaryocytes and the significance which should be attached to an increase of the former or the presence of the latter in the circulation. In a paper entitled "Megakaryocytes in the peripheral circulation," Minot (1922) pointed out that an increase in circulating platelets was usual whenever megakaryocytes were present in the peripheral blood, with the exception of myelogenous leukemia in which, despite megakaryocytes, the platelets might still be normal and even decreased. Minot's general observation was that whenever megakaryocytes or fragments were found there was usually other evidence of a grave disturbance of marrow function, as suggested by the simultaneous presence of immature cells of either the white or red cell series, or both. This was an early conception of the phenomenon nowadays known sometimes as leuko-erythroblastic anemia or, sometimes as a leukemoid blood picture caused by a nonleukemic disease.

As to myelogenous leukemia, in which primitive leukocytes (and usually red cells) were already present, Minot suggested that the appearance of megakaryocytes might be a sign of an acute exacerbation of the disease, he observed that when megakaryocytes appeared, the blood picture often changed from myelocytic to the terminal myeloblastic predominance.

Minot's general deductions were that since neither myeloblasts, nor nucleated red cells, nor megakaryocytes are found normally in the blood stream, then the finding of any or all of these cells pointed to a serious alteration in the mechanism regulating the emergence of cells from the bone-marrow into the circulating blood, in such cases, the marrow was subject to great strain, the pathologic process underlying the regulating mechanism was varied, since the immature cells occurred in the blood not only when there were 'structural changes in the marrow,' as in myelogenous leukemia, but also with other changes, 'probably functional, as in pneumonia and sepsis'.

Nowadays, one could add a number of other diseases which bring about "structural changes in the marrow," to Minot's example of myelogenous leukemia. An ability to hint at a correct diagnosis in these other diseases, which include carcinomatosis and Hodgkin's disease of bone, myelomatosis, osteosclerosis and myelosclerosis, Cooley's anemia and lipomatosis of the bone marrow (Rosenthal and Erf, 1943) can make or mar a hematologist, who must always be on the alert when he is confronted with a leukemoid blood picture.

Minot's suggestion of the significance of megakaryocytes was, therefore, an observation of fundamental practical value.

In a later publication, Minot and Buckman (1923) drew attention to the fact that megakaryocytes may share in the hyperplastic process of both leukemia and erythremia (polycythemia vera) and that in the former condition, the megakaryo-

From the Cambridge University Medical School, Cambridge, England

cytes may sometimes appear to be more involved than the leukocytes, so that the blood might indeed be flooded with megakaryocytes and their derivatives, the platelets. For a time, the leukemic process might seem to be almost restricted to the megakaryocytes, even as frank erythremia or leukemia cause varying degrees of pathologic activity of myeloid or erythroid tissue in conformity with a definite type. This paper has sometimes been quoted as suggesting a megakaryocytic type of leukemia, but such is a misrepresentation of Minot and Buckman's views, which go no further than to say that the disease process "appears to be" confined to the megakaryocytes. When taken in conjunction with Minot's (1922) earlier paper the significance of megakaryocytes in erythremia would seem to be a hint that the disease was in process of transition to some complication, possibly to the malignant erythro-leukemic form or to the terminal stage of a "spent" hyperplastic marrow which is becoming sclerosed. This last, as I shall presently show, is the more probable explanation, in view of the frequency with which megakaryocytes and abnormal platelets are found in the blood in myelosclerotic conditions.

Minot and Buckman (1925) followed up their first paper by another on "The Blood-platelets in the Leukemias," in which they concluded that the platelet count yielded useful knowledge for guiding treatment and for appraising the state of the leukemic patient. They observed that the platelets, especially in myelogenous leukemia, might be greatly increased or much reduced, whereas in the acute leukemias and the chronic lymphatic type it was usual to find the platelet count below normal. They noted that petechiae and hemorrhages were often associated with platelet decrease, and that hemorrhages, though not petechiae, might be found in chronic myelogenous leukemia, even when the platelets were greatly increased.

These three of Minot's early papers emphasize four important points, of which some are nowadays accepted as commonplace, though others are not widely known.

- 1 That megakaryocytes in the circulation are an indication of a serious disturbance of the bone-marrow. The fact must be taken into account when framing a prognosis.

- 2 That the bone-marrow disturbance is commonly leukemic in origin, but not always so. In the latter case, there is frequently a leuko-erythroblastic anemia, and the causes of such must be considered.

- 3 That when megakaryocytes appear in the circulation in leukemia or erythremia, they indicate of an impending change in the character of the disease.

- 4 That the hemorrhagic manifestations of leukemia are not due entirely to reduction in platelets.

MEGAKARYOCYTIC LEUKEMIA

Boros and Korényi (1931) described a case which they designated as megakaryoblastic leukemia. The case was severely anemic and had a leukocyte count of the order of 200,000 cells per cu. mm., among which the most primitive cells were described as large mononuclear leukocytes 10-25 μ in size, megakaryocytes, typical and atypical, complete and fragmented, were numerous in the blood. The clinical course of the disease as well as the postmortem description, suggest a diagnosis of

an acute termination of myeloid leukemia. Indeed, there can be little doubt that Boros and Korényi were observing no more than what Minot had described years before—the appearance of megakaryocytes in the circulation in myelogenous leukemia.

The literature also contains a number of reports under such descriptive names as “chronic nonleukemic myelosis” (Hickling, 1937, Carpenter and Flory, 1941), “aleukemic megakaryocytic myelosis” (Favre et al., 1934) and “myeloid megakaryocytic hepato-splenomegaly” (Downey and Nordland, 1939). Most of the cases described under these various titles have exhibited a leuko-erythroblastic anemia, with megakaryocytes and their fragments in the peripheral blood (as much as 26 per cent of all nucleated cells in Carpenter and Flory’s case). The spleen and liver have been enlarged, but seldom the lymph glands. Sections of the spleen, the bone marrow and even the liver, as well as sites of extramedullary hemopoiesis have shown numerous megakaryocytes. Nearly all such reports concern cases of myelofibrosis, and the frequency with which the megakaryocytic phenomenon is prominent in this condition has been well presented and illustrated in the account given by Rosenthal and Erf (1943) of 17 cases of myelofibrosis and one of osteopetrosis (Albers-Shonberg disease). The megakaryocytic tissue in the spleen and other organs arises from myeloid metaplasia, sometimes the process has been so prominent that authors have put forward the idea of a megakaryocytic leukemia. This cannot be accepted on the evidence presented. It would seem that myelofibrosis is the fundamental factor in producing this megakaryocytic type of metaplasia, whether the underlying cause of the fibrosis be idiopathic, or the “spent” stage of polycythemia, or even myeloid leukemia and other invasive conditions (carcinomatosis, etc.) of the marrow. In practice, whenever megakaryocytes, fragments, giant or bizarre forms of platelets, or even gross platelet increase, are found in the circulation, the question of myelofibrosis should be considered. Other small practical points can each or severally support the diagnosis. These include the evidence afforded by the other features of the blood count, by sternal puncture, and more especially by sternal biopsy, by radiologic examination of the bones with suitable controls of the same age group and, if thought necessary, by splenic puncture.

The result of sternal puncture is usually disappointing on the positive side. This in itself should raise suspicion when the accomplished operator is unable to obtain a satisfactory marrow sample by puncture, and especially if the bone feels gritty on puncture. The sample usually contains few cellular elements derived from the marrow, but either giant platelets or megakaryocytes are highly suggestive. In such cases, sternal biopsy should be performed. With a section, the fibrous nature of the marrow is revealed, and the lack of cellularity often associated with numerous megakaryocytes provides a diagnostic picture. Radiologic examination of the bones occasionally shows mottled rarefactions or irregular condensations in the cortices, which need to be compared with appropriate controls taken at the same time and with the same exposure (Hynes, 1940). Splenic puncture sometimes reveals the characteristic myeloid metaplasia with many megakaryocytes.

The following is a brief summary of a case recently referred to me for adjudication

by The Ministry of Pensions, it illustrates the confusion which may arise in patients who exhibit splenomegaly with leuko-erythroblastic anemia—a confusion which becomes more confounded under service conditions, when the patient moves from one hospital to another

REPORT OF CASE

Sergeant B E P was examined on re-enlistment in 1940, at the age of 38, and placed in Category A1. He had an uneventful service until, during the campaign in N W Europe in 1945, he reported sick with vague pain in the left upper abdomen. He was found to have a spleen enlarged to $2\frac{1}{2}$ fingers breadth below the costal margin, the liver was not enlarged. The blood count, performed under field conditions, was reported as Hb 13 Gm per cent, red cells 4.5 million per cu mm, leukocytes 6.5 thousand per cu mm, with no exact differential, though the report stated that 250 cells were abnormal, including myeloblasts, myelocytes, metamyelocytes and some cells of 'unknown origin', there were also a few early and intermediate normoblasts.

The man was evacuated from Europe and reinvestigated in England. The record of the blood count was Hb 13.8 Gm per cent, red cells 4.4 million per cu mm, leukocytes 6.2 thousand per cu mm, with 3.6 per cent myelocytes, 0.4 per cent myeloblasts, 0.8 per cent metamyelocytes, 2 megakaryocytes and 0.8 normoblasts per 100 leukocytes. Investigations included the exclusion of syphilis and glandular fever and a diagnosis of aleukemic leukemia was made. A blood count a month later was approximately the same, save that many giant platelets were observed. At the same time, a sternal puncture was performed, which showed essentially the same cell content as the blood, except for a slightly higher proportion of myelocytes and larger numbers of giant platelets and 2 megakaryocytes per 100 nucleated cells.

The patient then had a number of medical boards, where he was labelled ? leukemia, ? Hodgkin's disease, ? Banti's syndrome. At one of the boards, it was noted (without comment) that the patient was high colored and had a blood pressure of 160/90. He was discharged from the Army shortly afterwards. He worked as male nurse for two years, and was then re-examined on account of his pensions appeal. He stated that he had gone down hill a little, but was reasonably well. His blood pressure was 180/110, and there was some left ventricular hypertrophy, the spleen was enlarged to three fingers breadth below the costal margin, and the liver was easily palpable. The blood showed no increase in the anemia, the leukocyte count was 6.3 thousand per cu mm, with 8.5 per cent of abnormal cells, of which 0.5 per cent were myeloblasts, 2.5 per cent unidentified cells, and the remainder either myelocytes or metamyelocytes, there were 3 megakaryocytes and 4 normoblasts per 100 leucocytes.

Thus, during the intervening two years, the character of the leuko-erythroblastic anemia had not altered significantly, nor, indeed, had the clinical state greatly deteriorated. The spleen had become more enlarged, the liver had become palpable and the blood pressure had risen. The true nature of this man's disease, which might have been suspected from the outset by reason of the hematologic findings, is amply confirmed by the subsequent history and later records.

Most of the points relative to the title of this article, which is virtually the title of Minot's original (1922) paper, can be extracted from the above case record, and expressed as a

SUMMARY

1 Leuko-erythroblastic anemia, with leuko-erythroblastosis, rather than anemia, when associated either with the presence of megakaryocytes or giant platelets in the circulation, is very suggestive of the myeloid metaplasia so commonly found with myelofibrosis.

2 Associated splenomegaly with subsequent slow progress to hepatomegaly and a tendency to hypertension are confirmatory clinical features

3 Sternal puncture may or may not confirm the diagnosis, but if the specimen contains megakaryocytes, the fact is highly significant. Difficulty in piercing the bone or in obtaining a satisfactory marrow sample are points in favor of a myelofibrosis, which should be confirmed by the histologic examination of a trephined specimen

4 Controlled radiologic examination of the bones is sometimes of value in establishing a diagnosis in the idiopathic disease

5 A similar blood picture may occur with polycythemia vera, with myeloid leukemia and, occasionally, with other conditions in which invasion of the bone-marrow occurs. In polycythemia vera the finding suggests a terminal phase of exhaustion, in myeloid leukemia, likewise, the megakaryocytic phenomenon is usually an ominous sign of the terminal phase

6 When megakaryocytes are found in the circulation a diagnosis of myelofibrosis should always be considered

This short and simple article, which draws attention to some of George Minot's early work, brings with it the greetings of the entire staff of The Cambridge University Medical School to a great physician

THE ACTIVE PRINCIPLE IN THE LEUKOCYTOSIS-PROMOTING FACTOR OF EXUDATES

By VALY MENKIN, M D

THE earlier studies of the writer have demonstrated that the leukocytosis accompanying many inflammatory processes is referable to the liberation at the site of inflammation of a factor closely associated with the pseudoglobulin fraction of exudates ^{1, 2, 3} The factor per se offers a reasonable explanation for the mechanism of leukocytosis with inflammation This factor not only induces a discharge of immature leukocytes into the circulating blood,¹ but it also is capable of producing a hyperplasia of granulocytes and of megakaryocytes in the bone marrow ⁴ The factor (abbreviated as the LPF) is active on human beings, thus suggesting possible clinical application ⁵ It has been found to be active on guinea pigs This animal may well serve as a convenient assay animal ⁶ In as yet unpublished studies, it has been found that the LPF reinforces the leukocytosis caused by an already existing inflammation This may be significant in the usage of the material in clinical cases with inflammatory processes It is quite conceivable that the factor may be utilized as an adjunct to the antibiotics

The leukocytosis-promoting factor has always been recovered in the form of a pseudoglobulin Recent studies in association with Dr G Cooper and Mr M L Dillon at Duke University suggest that the LPF seems to be distributed primarily between the α_1 and α_2 globulins of exudates In the present communication evidence is furnished which suggests that the active group in the pseudoglobulin molecule of exudates is a relative simple polypeptide

EXPERIMENTAL

The leukocytosis-promoting factor (LPF) utilized in the following observations has been obtained from pleural exudates in dogs previously injected with 1.5 cc of turpentine as described in the past ⁷ The scheme of extraction can be briefly restated by referring to the diagram on p 940

The material when freshly obtained appears as a fluffy, white powder which is extremely soluble in an aqueous medium It is active in dogs, inducing a discharge of immature white cells into the circulation

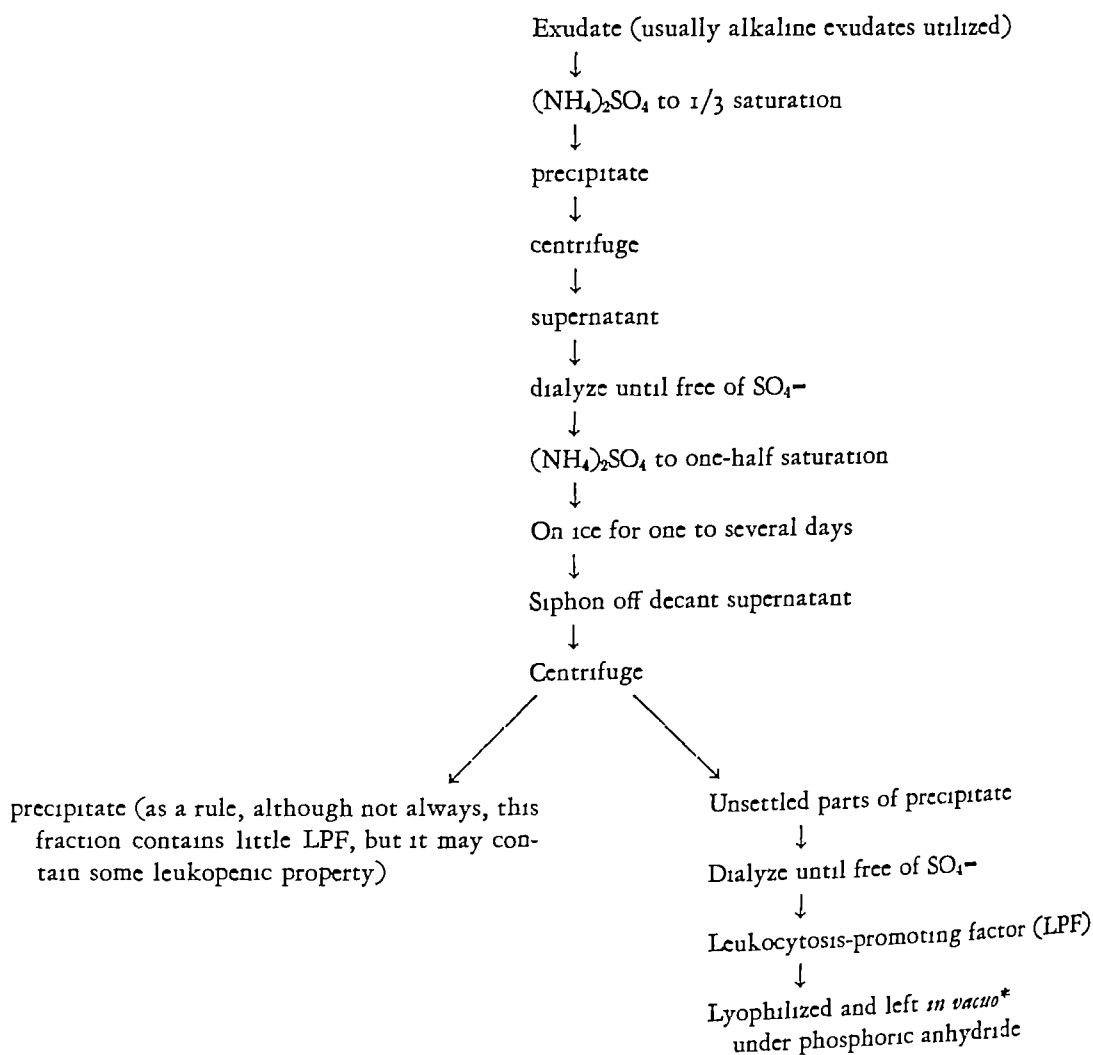

After several months, a curious change occurs in the material It seems to lose its solubility, becoming quite insoluble in physiologic saline, and at the same time the material loses its biologic activity It now has either no or little activity in causing a rise in the number of circulating leukocytes It seems as if a spontaneous

From the Agnes Barr Chase Foundation for Cancer Research, Temple University School of Medicine, Philadelphia Presented before the Philadelphia Pathological Society on March 13, 1947

The aged samples of leukocytosis-promoting factor used in this study were for the most part prepared at Duke University School of Medicine Aided also in part by a grant from the Bristol-Myers Company of New York

This is No 37 of a series entitled 'Studies on Inflammation'

denaturation has occurred. If the material is then centrifuged, the now insoluble part of the precipitate may even induce a leukopenic effect in contrast to the original leukocytosis-promoting property which it possessed. This, however, is not consistently true. At times it has either no activity, or at most a weak activity. On the other hand, if the supernatant phase of the insoluble aged LPF is injected

into the blood stream of a normal dog, considerable activity is obtained. The supernatant fraction induces a rise in the number of circulating leukocytes. It appears as if aging of the LPF causes a spontaneous denaturation into a relatively inactive and insoluble part. It splits off the active principle in the form of soluble component. The data of several such experiments appear in table I. It is clear that when 10 to 20 milligrams of aged LPF (3-6 months old) is treated with about 10 cc of saline, stirred, and centrifuged, the supernatant part yields considerable activity when injected into dogs. There is an increase of about 64 per cent in the number of circulating leukocytes (table I). The evidence indicates that the active

* Determination on three samples of LPF have yielded a recovery on the average of 12.8 milligrams of LPF per cc of exudate.

principle is liberated *in toto* as a soluble component from the now insoluble and aged sample of leukocytosis-promoting factor. The course of one such experiment is shown in figure 1.

TABLE 1—Effect of a Soluble Fraction Derived from Aged LPF (3–6 months old) on the Leukocyte Level

Dog No	Amount of original LPF from which soluble fraction derived	Basal no. of white blood cells	Maximum no. of white blood cells within 3–6 hours following administration of material
	mg	cu mm	cu mm
3-T	10	18,850	30,250
3-T	14.5	19,000	46,125
8-D	14	11,000	27,175
5-T	13.5	16,975	24,050
6-T	14	19,000	22,250
8-T	11.5	16,950	27,300
8-T	17	18,700	20,100
9-T	10	16,000	25,700
10-T	20	9,800	16,850
11-T	20	14,700	24,450
Average		16,097	26,425*

* Percentage increase in leukocyte level = 64.2%

FIG. 1. EFFECT OF SUPERNATANT FRACTION FROM AN OLD SAMPLE OF LPF ON THE LEUKOCYTE LEVEL
Dog 9-T. Supernatant from 10 milligrams of 5 months old LPF employed.

In view of this observation, it became of interest to determine whether a proteolytic enzyme would inactivate the leukocytosis-promoting factor when freshly recovered as a soluble pseudoglobulin from exudates. The LPF was extracted from exudates of dogs, as described above. Various quantities of the factor in the fluid

state were treated with crystalline trypsin in amounts varying from a mere pinch of the enzyme to 2 milligrams. The length of incubation with the LPF was also variable, lasting from about one hour to over twelve hours. The treated LPF failed to be inactivated by tryptic digestion. The observations are assembled in table 2. It is quite clear that the addition of trypsin has failed to inactivate the factor. Following such digestion the injection of the treated material still caused a rise of 111.5 per cent in the number of circulating leukocytes (table 2). The course of an experiment is graphically shown in figure 2. Trypsin is known to hydrolyze complex proteins, and also the products of peptic digestion to the peptide stage.⁸

TABLE 2.—*Effect of Tryptic Digestion on the Activity of the Leukocytosis-Promoting Factor*

Dog No	Material injected	Basal no of white blood cells	Maximum no of white blood cells within 2-6 hours following injection of treated LPF with enzyme
		<i>cu mm</i>	<i>cu mm</i>
11-T	13 cc LPF + pinch crystalline trypsin	12,100	24,600
12-T	18 cc LPF incubated overnight with trypsin	7,225	11,300
16-T	20 cc LPF incubated with trypsin 2 hours	12,275	25,900
9-T	18 cc LPF incubated with trypsin 2 hours	10,200	30,900
17-T	17 cc LPF incubated 2 hours with 2 mgm trypsin	6,300	8,950
20-T	10 cc LPF incubated 1 hour and 5 minutes with 1 mgm crystalline trypsin	10,900	24,100
9-T	10 cc LPF incubated 1 hour and 25 minutes with approximately 1 mgm crystalline trypsin	10,750	21,750
Average		9,964	21,071*

* Percentage increase in leukocyte level = 111.5%

On the basis of the foregoing evidence, it is conceivable that the leukocytosis-promoting factor is not a protein at all, and therefore it remains intact when subjected to the influence of a proteolytic enzyme.

Yet when the newly obtained and active leukocytosis-promoting factor is heated for 30-35 minutes at 100 C, the whole molecule appears to be denatured and the LPF is likewise inactivated. The results of these experiments are summarized in table 3. When the LPF is exposed to such temperature, the material is completely inactivated. The LPF now yields a rise of 6 per cent in the number of circulating leukocytes in contrast to its original activity of 104 per cent (table 3). The course of such an experiment is illustrated in figure 3.

These observations simply indicate that the LPF is thermolabile, but neverthe-

less that it may be merely associated with the pseudoglobulin molecule without being an actual part of it

FIG. 2 THE FAILURE OF TRYPSIN TO INACTIVATE THE LPF

Dog 20-T 10 cc of LPF + 1 milligram of trypsin incubated for 1 hour and 5 minutes before administering to the animal

TABLE 3 —Effect of Heat (at 100 C for 30-35 minutes) on the Activity of the Leukocytosis-Promoting Factor

Experiment No	Amount of LPF used	Basal white cell count in experiment with unheated LPF	Maximum white cell count 3-6 hours following administration of unheated LPF	Basal white count in experiment with heated LPF	Maximum white cell count 4-6 hours following administration of heated LPF
	mg	cu mm	cu mm	cu mm	cu mm
1	20	8,500	17,400	9,375	9,550
2	19	9,425	19,500	7,350	8,350
3	17	10,575	16,550	8,825	8,400
4	25	11,800	27,950	9,425	10,600
5	23	11,000	23,250	13,275	14,150
Average		10,260	20,930	9,650	10,210

Percentage increase in leukocyte level with unheated LPF = 104%

Percentage increase in leukocyte level with heated LPF = 6%

Such an interpretation is, however, not consistent with subsequent facts. When now the active supernatant or soluble fraction obtained from aged LPF is evaporated to dryness on a steam bath, its activity remains essentially intact. Evapo-

ration of the active supernatant material even over a steam bath fails to inactivate the principle. These experiments are collected together in table 4. When such brittle, dried material obtained by evaporation over a steam bath is heated for 30-40 minutes at 100 C, the active principle fails to be inactivated (table 4). The active supernatant material when evaporated to dryness forms brittle flakes which

FIG 3 THE INACTIVATION OF THE LPF BY HEAT

Solid line indicates Dog 33-T 25 milligrams of LPF administered. Broken line indicates Dog 30-T 25 milligrams of LPF inactivated by heating at 100°C for 35 minutes.

are insoluble in an aqueous medium. Heating again to 100 C such insoluble material fails to decrease its potency. Its injection in dogs induces a rise of 114.7 per cent in the level of circulating leukocytes. This observation definitely indicates that the LPF can be recovered from aged exudates as a highly thermostable substance. Experiments of this sort appear in figure 4. Such observations would preclude the interpretation that the leukocytosis-promoting factor is a thermolabile substance adsorbed to the pseudoglobulin molecule.*

* The insoluble brittle flakes obtained when evaporating the active supernatant to dryness on a steam bath are biuret and ninhydrin positive.

TABLE 4 —Effect of the Soluble Fraction Derived from Aged LPF When Evaporated to Dryness on Steam Bath and also When That Dried Fraction is Boiled for 30-40 Minutes

39-T†	28	14,750	43,050
Average		13,275	28,500‡

* Percentage increase in leukocyte level = 97.1%

† The evaporated material to dryness has in addition been subjected to boiling for 30-40 minutes

‡ Percentage increase in leukocyte level = 114.7%

FIG. 4 THE ACTIVITY OF THE EVAPORATED SUPERNATANT FRACTION OF OLD LPF

Solid line indicates Dog 11-T. Suspension of supernatant fraction from old sample of LPF, evaporated to dryness and suspended as insoluble material. Broken line indicates Dog 11-T. the insoluble material was obtained by evaporating to dryness the supernatant fraction of an old sample of LPF. This was then heated for 30 minutes at 100°C. The procedure essentially failed to inactivate the material.

Polypeptides are known to be highly thermostable.⁹ For this reason the amino acid nitrogen before and after hydrolysis was determined on several samples of the active supernatant phase from an aged sample of LPF. These observations are as yet preliminary, but the measurements from such samples indicate in each case a rise in the amino acid nitrogen following acid hydrolysis. The actual figures obtained on such samples before and after hydrolysis are listed in table 5. These

TABLE 5 — *The Amino Nitrogen Content in the Active Principle of the LPF before and after Hydrolysis*

observations suggest very strongly that the active principle is a relatively simple polypeptide.

DISCUSSION

The foregoing observations are consistent with the interpretation that the active principle in exudates, which reasonably explains the mechanism of leukocytosis with inflammation, is a relatively simple polypeptide.*

Besides the theoretic significance of this fact there is a possibility that the above observations may have practical application. The canine leukocytosis-promoting factor has been shown to be effective in human beings.⁵ The active factor has, however, been shown not to be too stable with time. A spontaneous denaturation occurs whereby the material loses its initial solubility. The present observations indicate that in spite of these changes the LPF is split off as a soluble and thermostable component. Its biologic activity remains undamaged. In this way it is conceivable that the leukocytosis-promoting factor of exudates can be preserved for long intervals in spite of age. These facts definitely suggest further practical use of this factor.

CONCLUSIONS

The leukocytosis-promoting factor of exudates appears to be a relatively simple polypeptide attached to the pseudoglobulin of exudates when extracted from the latter.

* The active principle is primarily nondiffusible from the active supernatant fraction of an aged sample of LPF. This would tend to indicate that the factor is somewhat larger than an amino acid.

This has been found by a study of samples of leukocytosis-promoting factor which have become insoluble by aging. Nevertheless, the active material has been found to be liberated as a water soluble component which is highly thermostable.

THE PLACE OF THE SPLEEN IN THE ENDOCRINE SYSTEM

By ARDREY W. DOWNS, M.D.

FROM being considered as of no use to the organism the spleen has come to occupy a rather insecure position as a gland of internal secretion. The purpose of this article is to try to show how this change has come about. A wide variety of functions has been assigned to the spleen from time to time, most of them involving the life cycle of the blood corpuscles. The spleen has been stated to manufacture red blood corpuscles and, on the other hand, it has been claimed that red corpuscles are destroyed in this organ. In the same way the spleen has been regarded by some as a place where white blood corpuscles are produced and by others as a place where they are destroyed. Evidence of an endocrine function of the spleen is still meagre and to some extent conflicting.

It is necessary to touch briefly on the background. The spleen was known to the ancients, the Greeks considering it as inessential to life. Aristotle refers to it and Erasistratus states that it is useless. It was regarded by the Greeks and Romans as detrimental to a runner and this idea persisted at least to the time of Shakespeare. It is frequently stated that the ancients removed the spleens of runners to increase their speed.

Splenectomy is said to have been performed in Europe in the sixteenth century. Moynihan¹ gives an account of the operation performed by Zaccarelli as written by an Italian physician, Leonardo Fioravanti, for the removal of the spleen from a woman 24 years old. Apparently she made a prompt recovery and suffered no ill effects. Moynihan points out that the suggestion has been made that the mass removed was an ovarian cyst. At least two other removals of the spleen are stated to have taken place during this century. During the seventeenth century two splenectomies are recorded, both of which seem to be reasonably well authenticated. In both cases the reason for the operation was knife wound in the left side with prolapse of the spleen.

The first experiments known to have been performed on animals in a study of the spleen, as described by Moynihan,² were carried out by Malpighi in 1669, Clarke in 1676 and Zambeccari in 1680. Malpighi ligatured the splenic artery and vein in a dog. Subsequently the spleen underwent complete atrophy and the liver enlarged. Both Clarke and Zambeccari performed splenectomies on dogs. No significant change was observed.

In 1841 Bardeleben³ published the results of the first carefully planned experiments directed toward elucidation of the function of the spleen. The results of complete removal of the organ were briefly these: a transitory decrease in the number of red, and an increase in the number of white, corpuscles in the circulating blood, an increase of activity of the bone marrow and lymphatic glands, no apparent ill effect on life. These experiments are particularly noteworthy because of the care with

From the Department of Physiology and Pharmacology, University of Alberta, Edmonton, Alberta, Canada.

which they were planned, the thoroughness with which they were carried out and the conclusions drawn

It was at this time that general consideration began to be given to removal of the spleen as a therapeutic measure. The results of Bardeleben's experiments gave support to the belief that the spleen was not necessary and splenectomy came to be employed more and more. Collier¹ recounts 29 cases of splenectomy reported to 1882. Of these, 13 were for wandering spleen, enlargement (described as "simple") and hydatid cysts. Eight of these were regarded as successful. In the other 16 cases "leukocythemia" was present. None recovered. These results made it clear that splenectomy was neither a sound nor safe procedure for leukocythemia.

A relationship of the spleen to hematopoiesis was recognized as a result of Bardeleben's experiments, which were confirmed by other investigators. The unsuccessful outcome of extirpation of the spleen in leukocythemia led to a turning of attention to the anemias. At the beginning of the twentieth century any syndrome of splenic enlargement and anemia was classified as a splenic anemia. If the spleen were responsible for destruction of red blood corpuscles then it seemed to follow that a condition such as pernicious anemia should be benefited by removal of the organ. Consequently, during the second decade of the century splenectomy was resorted to in a number of these cases. The results were inconclusive.

During this time Whipple, Hooper and Robschelt had been doing fundamental work on the anemias. Their report⁵ on the influence of meat, liver and various extractives on blood regeneration following simple anemia in dogs, produced by bleeding, is the foundation on which was developed our present knowledge of blood formation. From this study came the use of liver in pernicious anemia. Minot and Murphy⁶ found that feeding one-half pound of liver daily brought about improvement in patients with pernicious anemia. It later became clear that the fraction of liver which was curative in pernicious anemia was not the one which was effective in the anemia of bled animals. These discoveries led to the abandonment of the surgical procedure of splenectomy as a mode of treatment of anemia.

With the rising interest in internal secretions the spleen was not neglected, though it did not receive as much or so wide-spread attention as some other endocrine glands. During this period among the most notable workers was the group headed by Pearce, with Musser and Krumbhaar and a large number of associates. Among others on this continent who were interested in trying to establish something definite as to the way in which the spleen functions were Leake, Holloway and Blackford, Eddy and Downs. In Europe probably Danilewsky, Stradomsky and Mouzon were particularly interested in the physiology of the spleen.

Investigation of the part that the spleen plays in the formation and in the destruction of blood cells has followed largely four lines. Microscopic examination of the spleen, the counting of the cells in the blood going to and coming from the organ, the results of splenectomy, and the effects of administration of splenic substance or extract.

During a period of about fourteen years centering on the second decade of this century Pearce and his associates carried out many experiments intended to throw light on the function of the spleen. Dogs were the animals used. In 1913 Musser and

Krumbhaar⁷ stated that after splenectomy anemia usually develops quickly and reaches its height in from three to six weeks, then the blood picture approaches the normal after about three to four months, with complete return to normal in five to ten months. Accompanying this is marked leukocytosis, which reaches its height in twenty-four hours but persists to a slight degree for several months. In 1912 Karsner and Pearce⁸ had reported an increased resistance of red blood corpuscles after splenectomy. This was confirmed the following year by Pearce and Peet⁹ who stated further, that the increased resistance cannot be explained on the basis of an increase in reticulated cells in the circulating blood. Practically all observers agree that after splenectomy the red blood corpuscles are less fragile than normally. Pearce, Krumbhaar and Frazier¹⁰ had concluded that the transient anemia following splenectomy is due to the loss of some substance that stimulates the bone marrow with a lack of blood formation, rather than to increased blood destruction. This conclusion was supported by the observation of themselves and others that it was relieved by the administration of splenic extract.

In 1920 Downs and Eddy¹¹ published results of the subcutaneous injection of single doses of splenic extract in rabbits on the number of red corpuscles in the circulating blood. The immediate effect was a temporary decrease in the number. It was thought that the decrease might be due to a direct hemolytic action of a splenic agent. There was frequently a very transient increase in the number of white corpuscles. In 1921 Eddy¹² enunciated the hypothesis that the spleen produces an internal secretion. This was based on the changes in the erythrocytes after splenectomy, the modification of the blood picture in hyperplasia of the spleen, and the specific effects on the red blood corpuscles of injection of splenic extract. Nothing was known of the chemical nature of the supposed hormone and it was difficult to formulate a consistent theory of its possible mode of action. He suggested that the chief function of the spleen is the removal from the circulation of disintegrated erythrocytes, that the splenic cells elaborate this material and thereby produce an internal secretion, that this internal secretion, possibly after modification by the liver, stimulates the erythrogenic function of the bone marrow and is used up in the manufacture of new corpuscles.

Danilewsky¹³ in 1895 was able to cause a marked increase in the number of red corpuscles in the circulating blood and also in the hemoglobin content of the blood by a single intraperitoneal injection of an extract of the spleen. Apparently he was the first to suggest that the spleen acts on the bone marrow. In 1916 Stradomsky¹⁴ had concluded that the immediate effect of the splenic agent was destruction of erythrocytes. The increase in production of red blood corpuscles by the bone marrow, however, went beyond the usual response to a reduction in the number of corpuscles in the circulating blood and he felt that this was explained by assuming the removal of a normal regulating action by a splenic hormone on the bone marrow.

In 1922 and 1923 Downs and Eddy¹⁵ ¹⁶ reported further experiments in which splenic extract was administered subcutaneously to rabbits daily for periods of from four weeks to fifteen weeks. These showed the appearance of reticulated cells in the circulating blood in a proportion much greater than normal, the presence of

nucleated red corpuscles in the circulation, and an increase in the resistance of the circulating red blood corpuscles. These results agreed with those obtained previously and appeared to confirm the theory of splenic action that had been proposed.

At this time Leake and Leake¹⁷ demonstrated that both extract of spleen and extract of red bone marrow are hematopoietic agents and that a combination of the two is more powerful than either one alone. In their opinion they act first by increasing the rate of production and second, by causing an extension of functioning red marrow. Leake and Evans¹⁸ followed the treatment of various types of anemia in humans by the use of desiccated spleen and red bone marrow combined in equal quantities. Improvement was obtained in grave secondary anemias, both active and chronic, in dietary anemias of infants and in menorrhagic anemias.

The development of the concept of the spleen as a gland of internal secretion has taken place gradually during the past quarter century. During later years it has been based almost entirely on pathologic and clinical observations. In 1916 Kaznelson¹⁹ showed that removal of the spleen was followed by a rise in the platelet count and clinical improvement in some cases of thrombocytopenic purpura. He concluded that the spleen had been exerting an excessive cytolytic action on platelets. Whether Kaznelson's conclusion was sound or not his recommendation that splenectomy be performed in cases of thrombocytopenic purpura was followed by the report of excellent results in 16 cases.²⁰ Troland and Lee²¹ in 1938 described a substance obtained from spleens that had been removed from patients suffering from thrombocytopenic purpura which caused a reduction in the platelet count when injected into animals. Wiseman and Doan²² in 1942 described a condition that they ascribed to hyperactivity of the spleen. The spleen was enlarged and the white blood corpuscle count low. They named it primary splenic neutropenia. Splenectomy was followed by an increase in the leukocyte count and improvement in the condition of the patient. They believe excessive activity of a splenic hormone to be the cause, without being able to determine what has led to this disturbance of splenic processes. In 1946, Doan and Wright²³ described primary splenic panhematopenia, in which there is a reduction of all formed elements of the blood, red corpuscles, white corpuscles and platelets. In these cases also splenectomy caused marked improvement.

This study of the spleen is not unmindful of the useful purpose served by the spleen as a reservoir of quickly available red blood corpuscles with their hemoglobin. Nor does it overlook the phagocytic activity of the gland. It is, however, concerned with a different problem. Moreover, it has been pointed out that the phagocytic action and the production of one or more agents affecting the red blood corpuscles in active circulation and the bone marrow may be closely related.

CONCLUSION

An attempt has been made to trace the scientific study of the function of the spleen from the time of ancient Greece to the present. Modern theory and experimentation have linked the organ with the formed elements of the blood. Gradually a theory of endocrine activity has been developed which relates the spleen to the corpuscle content of the circulating blood. A normal blood picture is due, in part at

least, to a normally functioning spleen. There is then the possibility of hyper- or hypoactivity and it seems reasonable to regard certain clinical entities as due either partly or wholly to disordered splenic activity. Those conditions in which it seems to be fairly well established that removal of the spleen should be considered are thrombocytopenic purpura, splenic neutropenia and primary splenic panhematopenia. Cases so far reported suggest strongly that the prognosis is much improved by splenectomy. What the later effect of absence of the spleen may be remains unknown. A clinical manifestation of hypoactivity of the spleen does not appear to have been recognized as yet.

SUMMARY

While the evidence for an endocrine function of the spleen is meagre and the exact nature of this action is not clear it does seem to be fairly well established that the spleen must be considered as an important part of the mechanism whereby a normal corpuscle, and possibly platelet, content of the circulating blood is maintained.

This regulation seems to be due to the production by the spleen of one or more hormones.

These hormones appear to affect the processes of the bone marrow and also may act upon the corpuscles in the circulating blood.

The conception of hyperactivity of the spleen in the human being seems to be firmly established but little is known of the clinical appearance of its hypoactivity.

A HEMATOPOIETIC PERIFOLLICULAR ENVELOPE IN THE RAT SPLEEN

By E B KRUMBHAR, M D , Ph D

IT IS well known that hematopoietic cells of various kinds occur normally in the spleen of rats and other rodents as well as of other animals. In addition to these lymphocytes and reticulo-endothelial cells found in the Malpighian follicles and accompanying small arterioles, these cells may also be found in the pulp, together with erythrocytes and occasionally neutrophils, eosinophils, plasma cells, megakaryocytes, myelocytes, and nucleated erythrocytes (Jaffé¹). These cells are usually described as occurring diffusely or in small clumps. It has apparently escaped general notice, however, that surrounding the Malpighian follicle is an envelope of hematopoietic cells which is fairly well circumscribed, lacks sinuses, is separated from the follicular cells by a shell or rind of connective tissue, and responds to hematopoietic stimuli differently than does the red pulp. Under certain pathologic conditions, it may appear to be more voluminous than the follicle, which it surrounds. To be sure, Jaffé speaks of a *Follikelhof* or *Aussenzone* from which the follicle is sharply separated, which Weidenreich⁴ called a *Randzone* and Strasser² a *Follikdaussenzone*. Strasser also noted absence of sinuses and a thin rind. Also, in a study of the toxicity of benzene in rats and other animals, Svrbely, Dunn and Von Oettingen³ noted "narrowing of the perifollicular collars of closely packed pale cells." Dr R D Lillie, in whose laboratory this work was performed, writes that he "conceives of this zone as possibly the pressure reducing mesh homologous to the ellipsoids of dogs and cats. Its conspicuousness is quite variable. To me [R D L] it has seemed to vary inversely with the blood content of the pulp and sinuses. It is often the principal site of hemosiderin accumulation." As will appear below, we too have found the area to vary greatly in size and content under different conditions and in general to have its size modified by the amount of blood in the red pulp. However, under our conditions, at least, it seems to be rather an auxiliary hematopoietic tissue, depleted when exposed to hematopoietic poisons, and exuberant during periods of active blood cell regeneration.

PRESENT STUDY

The preparations studied were mostly routine paraffin cut sections (6-8 micra in thickness) stained with hematoxylin and eosin. Other stains, such as eosin-methylene blue and azur 2-eosin were also used. Details of the records of the experiments tried, leukocyte and differential counts, and the weight and gross appearance of the spleen were of considerable help in evaluating the findings. During the examination of the hematopoietic system of several hundred rodents, chiefly adult rats, during the course of a study of the pathologic effects of mustard gas and other hematopoietic poisons, it soon became apparent that the spleen contained two rather distinct hematopoietic areas in addition to the lymphocyte-forming Malpighian

From the School of Medicine University of Pennsylvania, Philadelphia

follicles These were (1) small foci scattered through the red pulp, (2) the perifollicular areas already referred to The small foci were apparently composed of either myelocytic, erythrocytic, monocytic, or lymphocytic cells, or sometimes of mixtures In the case of the lymphocytes, they may have been about small vessels, which, as Jaffe notes, can be brought out with the perfused specimens, the cells of some of these foci have the same appearance as those in the envelopes about to be described As might be expected, these foci tended to disappear in the spleens depleted by poison, and to be large and widespread in recovery periods during active

FIG. 1 Normal rat's spleen Two Malpighian follicles (MF) with their central arteries appear, surrounded by the paler staining perifollicular envelope (PFE) The more open red pulp occupies the rest of the field (H-E, 150 X)

regeneration However, as so often is the case with different units of the hemopoietic system in the present state of our knowledge, they at times showed unexpected and unexplained responses

In sections of normal rats' spleens, the perifollicular areas are easily distinguished in the stained specimen as collars of nucleated cells, paler and larger than the adult lymphocytes of the Malpighian follicle The "collar," a term appropriate for the two dimensional section but not for what is obviously a three dimensional structure, varies in width from about 30 to as much as 200 micra It is separated from the follicle by a delicate but definite line of collagenous connective tissue which is

presumably a development from the follicular framework. This narrow rind contains a young type of fibroblast and sparse collagen fibers. The rind usually cannot be traced around the complete circumference. In one instance (rat 1630), a capillary was enclosed in this band for about one quarter of the perimeter. The cells of the perifollicular areas in normal spleens are mostly mononucleated, about the size of young lymphoblasts, the nuclei round and moderately full of chromatin, often with a deep staining central dot, and with scanty pale-staining cytoplasm. They show

FIG 2 Same section, showing part of the larger follicle and its collar. Note the curved rows of adult lymphocytes near the margin, separated by delicate connective tissue (which does not show in the photograph). The more homogeneous nature of the collar than of the red pulp is obvious (H-E, 320 X)

no gradation to the fibroblasts of the thin rind, nor do they resemble them in appearance.

They do not appear to be monocytes, as they have scanty cytoplasm that is not granular and never contains ingested material. The nuclei are never indented and show no characteristic nucleoli.

These cells were further investigated by making imprints of the freshly bisected surface of some 30 normal rats' spleens and comparing the stained imprint (May-Grünwald-Giemsa) with stained sections from the other side of the bisection. Successive imprints, a dozen or more per spleen, reproduced the same appearance.

with surprising similarity, given a marked, if superficial, resemblance to serial sections. Though the blood cells did not stain as well by this method as they do in good blood smears, the cells in question were easily identified. They were thought to be young lymphocytes by several colleagues as well as by myself. Compared to the small dark-staining nuclei of adult lymphocytes and normoblasts, in the imprints their nuclei were 50 per cent larger, paler, with coarse chromatin clumps and a tendency to condense around the nuclear membrane. The cytoplasm was mostly very scanty, where more abundant, it stained a very pale blue without granules or

FIG 3 Greatly depleted spleen of rat 6-2-7, dying seventeen days after nitrogen mustard gas poisoning. Both the follicle and collar have lost many cells, with a number of polys, immature red cells and debris present. Note the fibrocytes separating follicle and collar (H-E, 135 X)

vacuoles. Oxidase granules (benzidine stain) could not be demonstrated in their cytoplasm such as appeared in the neutrophils.

The possibility that these cells are immature monocytes or myeloid cells cannot be ruled out until studies can be made under living conditions, as in tissue cultures, and such items as their mode of growth and locomotion observed. Occasional larger round, heavily stained nuclei (immature cells) are found, and more sparsely and not constantly, normoblasts and adult erythrocytes, polymorphonuclear neutrophils and eosinophils, also large, pale vesiculated nuclei that are taken to be adult reticulo-endothelial cells. No megakaryocytes have ever been found in the collar, and no sinuses. The outer margin of the zone merges almost imperceptibly into the red pulp, the transition being chiefly determined by the appearance of

sinuses and more stroma and by the much greater number of erythrocytes. Sections that cut through the edge of a follicle may show a broader perifollicular than follicular area, or even none of the adult lymphocytes of the true follicle at all.

In the spleens depleted by various poisons of the lymphocytic and granulocytic cell series, the perifollicular collar may be represented by an almost empty circular band (except for an extremely scanty stroma) bounded on its two margins by a still recognizable follicular rind and the denser stroma of the red pulp. If the damaged spleen is congested, the empty collar stands out in bold contrast.

FIG. 4. Spleen of rat 6-1-3, killed while recovering from a non-lethal dose given three weeks earlier. Note the extremely wide collar of a follicle that is relatively small. The rectangle indicates the field of the next figure with an approximation of the width of some collars indicated. (H-E, 150 \times)

In spleens of rats killed three weeks to three months after the experiments, the collars usually but not always appear larger and paler than normal with larger cells and occasional mitoses present. More hematopoietic cells of several kinds, except the megakaryocyte, are found interspersed and sometimes in concentrated foci that suggest local production. As the collars contain only few erythrocytes, the more the red pulp is congested, the more conspicuous the relatively pale, reddish purple, collars appear between the dark blue of the follicle and the red of the erythrocytes. In rare instances, however, hematocytic regeneration in the pulp foci may be so

extensive that more erythrocytes are found diffused through the collars together with their usual cells than in the pulp, which is hardly recognizable as splenic tissue

Turning to other rodents—in the mouse spleen, the collar is less developed, nucleated cells are much more frequent throughout the pulp and the transition from follicle more gradual. The "collar" therefore is almost indistinguishable, though occasional suggestions of a connective tissue rind may be seen, beyond which the lymphocytes are more condensed than farther out in the pulp. Here, too, the numerous megakaryocytes in the pulp aid in the differentiation

FIG. 5 Same section (800 \times) The beginning of the red pulp area is hard to distinguish, though the megakaryocyte (mega), sinuses (s), and RBC (to the right) are surely in the red pulp (H-E)

In the rabbit, the picture is more like that of the rat, except that "pale centers" (reticulo-endothelial cells²) may often be found in the topographic center of the follicle, they are rare in the rat. The rind of connective tissue is usually found, the limits of the follicle being indicated both by this pink staining strip and by a tendency for the sectioned tissue to separate at this place. The cell population of the collar varies as in the rat, with a fair number of nonlymphocytic cells that are not to be found inside the rind.

In the guinea pig, which may have pale centers in the follicles, both rind and collar are scanty and ill-defined, indeed, even their existence in places seems doubtful, though Jaffé says the collar is easy to find if perhaps narrow. When found, it has the same difference in cell population from the follicle as does that of the rat. In a few normal hamsters, the perifollicular tissue is also found to be less constant

and rich than in rats. Few if any myeloid cells are seen, ripe or unripe, and very few normoblasts and erythrocytes. The ring varies much in size, not being found at all in small follicles.

SUMMARY AND CONCLUSIONS

About the Malpighian follicles of several species of rodents, and especially prominent in rats, is a perifollicular envelope composed of hematopoietic cells that takes active part in hemolypopoietic changes.

The identity of the mononuclear cell comprising the greater part of this tissue has not been positively determined, it is probably a young lymphocyte. It is possibly the homologue of the pale centers of the Malpighian follicles in man and other mammals, though it has been found in rabbit spleens which also have pale centers. It should be possible to determine this identity by the use of a greater variety of stains, and of test poisons, and, if possible, of dynamic methods such as tissue culture and moving pictures.

The envelope is separated from the Malpighian follicle by a thin ring of collagenous connective tissue, but on its outer margin it merges gradually with the red pulp. It often contains a scattering of erythrocytes, normoblasts, polymorphonuclear neutrophils, and rarely eosinophils and pigment-bearing macrophages. Some of these cells were so greatly increased under the pathologic conditions first studied that colonization was suggested, they were later thought to have probably wandered in. The collar never contains megakaryocytes or sinuses or blood vessels of any noteworthy size.

Case Report

MONOCYTIC LEUKEMIA

By CARL J. GESSLER, M.D.

THE publication of detailed case reports may often be of value. A case of monocytic leukemia is reported here in detail, in the hope that it may throw some light on our knowledge of this condition.

REPORT OF CASE

The patient was a 36 year old, married white woman, who lived in Brussels. When first seen on August 8, 1946, her chief complaint was that of progressive weakness of several months' duration. The most interesting feature of the past history was a series of skin symptoms. In January, 1946, an itching erythema appeared on the inner aspect of both thighs, and, one month later, the forearms and neck became similarly affected. These manifestations disappeared about the middle of March. The patient stated that for about eight days at the beginning of July she had had some kind of eczema on the neck. A few days later, on July 18, numerous brownish-red, slightly itching papules had appeared on the trunk, and had persisted for about a week.

The patient was very pale, and her face was swollen. The spleen was not palpable, no lymph glands were felt, the liver was tender and felt 2 cm. below the costal margin in the mid-clavicular line. Blood laboratory examinations revealed the following: Hemoglobin 28 per cent = 4.37 Gm. per 100 cc., red blood cell count, 222 million per cu. mm., color index 0.6, total white blood cell count 50,500 per cu. mm. Examination of the stained smear (May-Grünwald, Giemsa) revealed the presence of numerous large cells with irregular nuclei. The differential count (based on 400 white cells) was as follows:

- 20.25% neutrophils (9.25% of them staff cells)
- 0% eosinophil
- 0% basophil
- 12.75% lymphocytes
- 56% monocytic cells of abnormal morphology 65.5 leukemic cells
- 9.5% paramyeloblasts
- 0.5% neutrophil metamyelocytes
- 1% neutrophil myelocytes
- 3 normoblasts were found per 400 leukocytes

Aspiration of the bone marrow by sternal puncture proved unusually difficult, finally, however, small lumps of whitish material were obtained, practically free from blood. The smear of the specimen was almost entirely made up of leukemic cells, which could be classified as pathologic promyelocytes or promyelocytoid paramyeloblasts. *Not one cell was seen in the sternal puncture preparation which was comparable with the monocytic type of cells found in the blood.*

The patient was seen again three weeks later and at that time her condition had deteriorated rapidly. Considerable edema of the face, extreme weakness and extensive ulcero-necrotic lesions of the mouth were noticed. The temperature was 39°C (102.2°F). A few brown macules, half a centimeter in diameter, remained from an extensive eruption of red spots which had appeared during the interval between the two examinations. The blood pressure was 120-40. Blood examination showed the following: Hemoglobin 11 per cent = 1.72 Gm. per 100 cc., red blood cells 1.04 million per cu. mm., and leukocytes 184,600 per cu. mm. The differential count was as follows:

- 3.25% neutrophils (1 staff cell)
- 0% eosinophil
- 0% basophil
- 4.25% lymphocytes
- 77.5% monocytic cells of abnormal morphology 92 leukemic cells

14.5 % paramyeloblasts

0.5 % plasmacyte

2 normoblasts were found per 400 leukocytes

The patient died on August 31

DISCUSSION

The ulcero-necrotic lesions of the mouth were perhaps particularly significant. Forkner¹ stated that such lesions are more constant and extensive in monocytic leukemia than in other varieties of leukemia. The cutaneous manifestations are also worthy of note. Some of them were atypical and probably allergic in origin,

FIG. 1. BLOOD SMEAR

while others, consisting of brown or red maculo-papulae, were more or less characteristic of the reticulo-endothelioses.

There seems to be no possible doubt as to the diagnosis of leukemia. However, opinions could differ as to the exact classification. A diagnosis of monocytic leukemia was substantiated by the high percentage of abnormal monocytic cells in the circulating blood. These cells are extremely polymorphous and can be divided into two main groups, although such divisions are always somewhat arbitrary. (1) The majority were large cells containing irregular nuclei without nucleoli, the pale blue protoplasm being entirely filled with a great number of very small azurophil granules, which are characteristic of the monocyte. (2) Other cells, very similar to the previous ones, had younger nuclei, containing nucleoli, and the fine azurophil granulation occupied only part of the protoplasm, sometimes being confined to the perinuclear zone. It is on the basis of these criteria that Osgood² distinguishes monocytes and promonocytes. In the first differential count, in a

total of 56 monocytic cells, 50 belong to the first group and 6 to the second, in the second differential count, on a total of 775 monocytic cells, 465 belong to the

FIG 2 BLOOD SMEAR

FIG 3 BLOOD SMEAR

first group and 31 to the second, which shows an increase of the more immature cells

However, as mentioned before, there was a marked discrepancy between the

blood smear and the marrow smear. Considering only the marrow smears one would have no hesitation in making a diagnosis of myeloid leukemia. The case could then be interpreted in two different ways. (1) If one believes that the monocytic cells of the blood are derived from the leukemic cells in the marrow, the case could be

FIG 4 BLOOD SMEAR

FIG 5 MONOCYTIC CELL WITH PSEUDPODE
(Note granules extending within the pseudopode)

termed *paramyeloblastic leukemia*. (2) When one assumes the monocytic cells of the blood are *not* derived from the leukemic cells in the marrow, but express a reaction of the reticulo-endothelial system elsewhere in a patient with myeloid leukemia which Oberling³ has called "reticulosés associés." Oberling has given instances of this association.

In our opinion, it would be an overextension of the concept of the "paramyelo blast" to consider, as such, the monocytic cells in the peripheral blood of our case

FIG 6 MARROW SMEAR

FIG 7 MARROW SMEAR

On the other hand, their morphology seems too definitely abnormal to regard them simply as a result of a simple reaction of the reticulo-endothelial system. Despite the lack of monocytes in the bone marrow, it was felt that there was strong evi-

dence for a diagnosis of monocytic leukemia, which can be defined further, according to the currently prevailing classification, as belonging to the Naegeli type (characterized by leukemic proliferation in the bone marrow) as opposed to the Schilling type (or leukemic reticulosis) characterized by proliferation of the reticulo endothelial system elsewhere than in the bone marrow

Author's note

It is interesting that the patient's brother died in 1942 at about the same age (35) of a mediastinal tumor. Unfortunately, no answer was received to our inquiries concerning the nature of this tumor, which might well have been a localized growth of reticulum cells.

THE "AXELRAD" MICRO TEST SLIDE

(U S Pat No 2302830)

FOR KLINE, MAZZINI AND B-J-L TESTS

For use in general flocculation and agglutination tests, blood typing, drop test reactions in micro and semi-microchemistry, as the flat bottoms and uniform depth of the cells reduce the sometimes objectionable shadows observed with slides or plates having spherical concavities

This slide should not be confused with concavity slides, which we also stock

- 606-B Single Slides at \$2 75 each
- " Dozen lots at \$26 00 per dozen
- " 3 Dozen lots at \$24 00 per dozen

SLIDE No 606-B

Bottoms of the cells are flat and slightly rounded at the periphery, which construction prevents capillary flow around the outer edge of the bottom and insure thorough shaking of the drop. Has twelve numbered mould pressed raised rings. Slide is ground at one end to provide space on which to write identifying marks, and bottom of slide is optically ground and polished. The rings and the plate are moulded in one-piece glass. Actual size of slide is $3\frac{1}{2}$ inches by $2\frac{1}{4}$ inches.

NUCLEAR STRUCTURE VERSUS NUCLEAR PATTERN*

By OLIVER P. JONES, PH D

INTRODUCTION

IN A RECENT study of primitive erythroblasts,¹ it was shown that cytoplasmic areas originally interpreted as hyaloplasm by hematologists actually represent negative images of underlying cell organoids—mitochondria and Golgi elements. This finding immediately unfolded many interesting problems concerning erythroblasts in general, especially since it was shown that cell organoids may be preserved in good dry smears. How long do mitochondria retain their vitamin A content? Do the more mature erythroblasts contain mitochondria which have lost their affinity for acid fuchsin and supravital dyes? How long do mitochondria persist in non-nucleated corpuscles of the primitive and definitive generations?^{2, 3} What happens to the chromophilic and chromophobic portions of the Golgi element as primitive erythroblasts mature?⁴ Do these elements contain vitamin C?⁵ How do these organoids respond under the influence of antipernicious anemia substances?

In order to investigate some of these problems various preparations were made from the 15 day rat embryonic liver. A study of lymphoid cells (i.e., any cell with basophilic, nongranular cytoplasm, regardless of its nuclear detail) by means of phase microscopy revealed the presence of more cell organoids, particularly mitochondria, in definitive erythroblasts than had been observed in primitive erythroblasts. Furthermore, most of these organoids were contained in the thin layers of cytoplasm above and below nuclei as seen in dry smears. Although it had been observed previously that some sudanophilic material may be distributed in these regions in primitive erythroblasts from 11 day rat embryos,¹ the significance of this finding was not appreciated fully until rat and human fetal liver material were studied. Since the implications derived from these observations might markedly alter present day concepts in practical and theoretic morphologic hematology,⁶ it was deemed necessary to forego the other problems and to undertake the present one dealing with nuclei as seen in dry smears.

MATERIAL AND METHODS

Most of the material used for the present investigation was obtained from 136 livers of 15 day rat embryos from 13 pregnant Wistar rats, blood from 11 and 15 day

From the Department of Anatomy, School of Medicine, University of Buffalo, Buffalo, N. Y.

*Presented in part before the Society for Experimental Biology and Medicine, University of Buffalo, May 3, 1947, Interdepartmental Seminar, University of Rochester School of Medicine and Dentistry, May 29, 1947, and the American Association of Anatomists, University of Wisconsin, April 22, 1948.

embryonic rat yolk sacs, and lymph nodes from adult rats. Human material was obtained from the livers of 4 fetuses ranging 3 to 4½ months old. * Dry smears of embryonic livers and lymph nodes from adult rats were made by touching their cut surfaces to a cover slip, smearing them slightly and then drying rapidly. Some of these were stained with the May-Grünwald-Giemsa combination of Pappenheim, using buffered distilled water for dilution. Others were mounted, unstained, in a drop of 10 per cent formalin (4 per cent formaldehyde), and ringed with vaseline for study by phase microscopy.¹ Some of these preparations have remained in good condition for 12-14 months. Moist smears following Zenker-formol fixation were mounted unstained in glychrogel for study by phase microscopy. In order to study both sides of stained blood cells, small square cover slip preparations were mounted in clarite on 24 × 60 mm cover slips. Supravital preparations were made by immersing the yolk sacs and embryonic livers in saline solutions of neutral red (1:10,000), dahlia violet (1:20,000) and janus green (1:20,000 and 1:40,000). The first two were also used in combination according to Baker.⁴ After the material had been in these solutions for fifteen to twenty minutes at room temperature, it was swished in a drop of the same solution on a clean slide in order to free some blood cells, cover slipped and sealed with vaseline. Small pieces of yolk sac were also flattened and mounted. Permanent mitochondrial preparations were made in a manner slightly different from that reported previously. Dry smears were fixed in a formol-Muller's fluid (1:9) for two to three hours, washed briefly in distilled water and placed in 1 per cent osmic acid for one-half to one hour in the dark. They were washed and stained with aniline acid fuchsin as described before.¹ The distribution and localization of lipoid material was studied with the aid of Sudan black.¹ The presence of vitamin A was detected by using the Carr-Price reagent.¹

Phase microscopy has been a great aid in studying the cytoplasm of unstained cells,¹⁻⁶ as well as in making optical sections through nuclei. Four diffraction plates were used as follows: 0.2A+0.25λ for a preliminary survey of material, 0.15A-0.25λ for detailed examinations and camera lucida work, 1.0B-0.2λ in conjunction with supravital preparations, and 2.5B-0.33λ alone or in conjunction with Sudan black preparations. The first diffraction plate produced bright contrast whereas the last three produced dark contrast.⁷⁻⁸ A Spencer research microscope equipped with apochromatic objectives and 15× compensating oculars was used.

OBSERVATIONS

A. Blood From 15 Day Rat Embryos

Although this paper deals chiefly with observations made on lymphoid cells in embryonic liver, it seems advisable to report results of certain preliminary studies on blood from the 15 day rat embryo. This material was obtained by pipetting blood from the heart or vitelline vessels.

1. *May-Grünwald-Giemsa Preparations.* Over two thirds of the cells were nucleated and about 85 per cent of these belonged to the primitive erythroblastic series or pre-hepatic generation. The cytoplasm usually stained polychromatophil and it

*Kindly furnished by the Department of Obstetrics and Gynecology, Buffalo General Hospital

contained some juxtanuclear light areas not unlike these referred to as the area of the cytocentrum. The nuclei were in various stages of pyknosis.

2 *Formol-Sudan Black Preparations* The most constant finding was a juxtanuclear clump of sudanophilic material. This appeared as a cluster of vacuoles (sudanophobic) in contact with solid sudanophilic spheres, or surrounded by sudanophilic rings or crescents. The majority of these clusters seemed to behave as a unit although a few were scattered throughout the cytoplasm. Some faintly grayish filaments and small spheres or granules were also present. In nearly every instance the pyknotic nuclei had a remnant of what appeared to be a nucleolus. It was a very rare occurrence to find sudanophilic material trapped between the nucleus and the cover slip, or beneath it.

3 *Phase Microscopy* Unstained dry smears of yolk-sac and heart blood mounted in 10 per cent formalin were examined with dark contrast phase microscopy lenses ($15A-\frac{1}{4}\lambda$ and $25B-\frac{1}{3}\lambda$). There was a remarkable degree of correlation between the morphology and distribution of dark structures as seen with phase microscopy and those seen in Sudan black preparations. The main difference was that the sudanophilic structures varied in color from faint gray to blue black, whereas the dark contrast structures appeared uniformly black. At no time did sudanophobic structures appear dark with phase microscopy. Pyknotic nuclei showed much more structure with phase microscopy than they did in May-Grunwald-Giemsa preparations. Nearly every nucleus contained one or more bodies which appeared to be the remnants of nucleoli. The large, non-nucleated primitive erythrocyte—not unlike some definitive erythrocytes^{2, 3}—frequently contained quite a few organoids.

4 *Supravital Studies* Mitochondria in cells freed from yolk sacs of 15 day rat embryos did not stain as intensely as they did in cells from 11 day rat embryos,¹ and very often they appeared more finely divided. Although some filaments were faintly green, the color was uniform throughout their entire length. In neutral red-dahlia preparations, the neutral red was usually limited to a juxtanuclear cluster of vacuoles. Sometimes one or more of these vacuoles would also be found elsewhere in the cytoplasm. In successful preparations the dahlia would stain rings, crescents and spheres associated with the neutral red vacuoles. When pressure was applied to the cover slip, the cells moved about in a rolling fashion. In such cases the juxtanuclear clump of neutral red vacuoles behaved as a unit, maintaining their relative position within the cell and with respect to each other.

5 *Comment* It was reported previously that freshly dried films of primitive erythroblasts from 11 day rat embryos preserved cytoplasmic detail to an extraordinary degree.¹ Preliminary studies indicate that the same also obtains for blood from the 15 day rat embryo. Structures in dry smears which appear as sudanophobic vacuoles, or as light vacuoles with dark contrast phase microscopy have the ability, in supravital preparations, to segregate a basic dye like neutral red. Some of these vacuoles may be surrounded with a sudanophilic ring or crescent which occasionally stains with dahlia in supravital preparations.

This staining in the nucleated primitive erythroblast with neutral red differs from that originally studied in the erythrocyte by Israel and Pappenheim⁴ and more recently by Ralph⁵ in that these vacuoles were not newly formed but pre-formed

structures demonstrable in the unstained dry fixed smear mounted in 10 per cent formalin and the living condition with phase microscopy Dustin¹⁰ has reported similar findings in erythrocytes of *Rana* and *Axolotl*, and he has identified these vacuolar structures with the Golgi element. Since preliminary studies on 15 day rat primitive erythroblast show that preformed vacuoles are surrounded by argen-tophilic as well as sudanophilic material, it seems that the mammalian primitive erythroblast has a Golgi element similar to that described for erythrocytes of lower vertebrates ^{10 11 12} Such a Golgi element or apparatus is certainly not an artifact produced by over osmification as claimed by Ralph³ for erythrocytes of the lower vertebrates

Newly formed neutral red vacuoles not associated with these juxtannuclear structures were present sometimes. Dustin¹⁰ has shown that these vacuoles appear when nucleoprotein is present. Apparently when neutral red acts on the cytoplasm of cells containing basophilic substances in a diffuse state, the nucleoproteins become partly separated in a newly formed liquid phase and are segregated along with the dye in vacuoles. This will be considered again in section B 2.

B *Smears of 15 Day Rat Embryonic Liver*

1 *Phase Microscopy* Until the present, all previous observations had been made on primitive erythroblasts. In order to determine whether or not the same conditions obtained for definitive erythroblasts (the second or normoblastic generation of red cells), unstained dry smears of embryonic livers mounted in 10 per cent formalin (4 per cent formaldehyde) were examined. A cursory examination of this material with a brightfield microscope revealed cells laden with numerous organoids, which were trapped between the nucleus and cover slip. Figure 1a shows the best detail which could be brought out by reducing the condenser diaphragm aperture to N A 0.45. When this same cell was examined with bright and dark contrast phase microscopy, it was possible to bring out the finer details of these organoids. This method showed that ring forms (like minute doughnuts) and filaments over the nucleus (i e, between the nucleus and cover slip) had the same morphology as organoids in the cytoplasm. As shown in figure 1, b and c, some of the filaments extend from the cytoplasm beyond the nuclear membrane and continue over the nuclear area. By careful focusing it was also possible to demonstrate that some ring forms had been trapped between the nucleus and cover slip over the nucleolar area. It was also noteworthy that optical sections of nucleoli by means of phase microscopy appeared more like those seen in tissue sections after Zenker-formol fixation than they did those in dry fixed smears after methyl alcohol fixation.

Similar observations were made on many cells in several preparations, one of which is illustrated in figure 1, d, e, and f. This, like the one above, corresponds to those illustrated by Maximow¹³ as large lymphocytes and cell 'A' (transition of a mesenchyme cell to pronormoblast) in the article by Kirschbaum and Downey¹⁴. Such a cell is very interesting because all of the organoids in the thin layer of cytoplasm over the nucleus (i e between the nucleus and coverslip) are either ring or elliptical forms ranged in a column one behind the other in a depression between two nucleoli. In the cytoplasm beyond the nuclear membrane, similar

forms are present but instead of being orientated on their edge or tilted, they are on their sides, giving the appearance of a circle or minute doughnut. These organoids are at a lower cytoplasmic level than those over the nucleus, consequently they are out of focus. In this cell, no filamentous forms are trapped between the nucleus and cover slip. In quite a few instances the filamentous forms beyond the nuclear membrane had a dilated terminal area which appeared to be forming the elliptical and ring-form organoids. Although this is beyond the scope of the present article, it would seem that the filaments are not increasing in length by the addition of

FIG. 1. Photomicrographs of unstained definitive erythroblasts (normoblasts) from 15 day embryonic liver mounted in 10 per cent formalin. Mitochondria are shown in layer of cytoplasm between nucleus and cover slip. Cells a and d, no phase, magnification 1835 diameters. Cells b and e, bright contrast phase, magnification 1820 diameters. Cells c and f, dark contrast phase, magnification 1820 diameters. All photomicrographs in figures 1 and 2 were furnished through the courtesy of the Research Division, American Optical Company, Scientific Instrument Division, Buffalo, N. Y.

material, but rather that they are becoming shorter by producing other forms. Granular and coccoid forms of organoids are also present.

The selection of 10 per cent formalin (4 per cent formaldehyde or Baker's formal calcium) as a fixing and mounting media was made on the basis that, after studying unstained cells by means of phase microscopy, they could be stained with Wright's stain or Sudan black. It is now known that the choice of this mounting media has the following additional advantages. First, phase microscopy works best when there are small optical path differences between the specimen and the surrounding

media.⁸ Baker¹⁵ has also pointed out that greater use should be made of aqueous media with a refractive index approximating that of water rather than ones in which the index is like that of glass. Another advantage in using this mounting media is that the cells in dry smears imbibe fluid and swell somewhat. This makes it possible to study more accurately optical sections through various cell layers above, through and beneath the nucleus.

Optical sections of numerous cells were made and studied with bright and dark

FIG. 2. Optical sectioning by phase microscopy of unstained definitive erythroblast (normoblasts) from 15 day embryonic rat liver mounted in 10 per cent formalin. Cells a, b and c show optical sections with bright contrast phase above, through and beneath nucleus respectively. Mitochondria appear bright. Cells d, e, and f show a similar series with dark contrast phase. Magnification 1820 diameters.

phase microscopy first through the thin layer of cytoplasm between the cover slip and the nucleus, then through the nucleus and finally through the thin layer on the other side of the nucleus. The cell in figure 2 is representative of this group. By using a fine adjustment control scale, these three levels had the following uncorrected vertical sizes, respectively 3, 2 and 4 microns. Optical sections through these levels showed that dry smears of lymphoid cells actually cause the nucleus to be sandwiched between two thin layers of cytoplasm which contain well preserved organelles. In figures 2b and 2e, the structures to the left and above the cell center

represent organoids out of focus which were actually in the layer of cytoplasm beneath the nucleus

A microscopist continually turns the fine adjustment control in order to bring as many structures into focus as possible and thereby gain perspective. Consequently, such a view is not well illustrated by a single photomicrograph. However, by making a camera lucida drawing it is possible to represent most of the structures found on either side of a given optical section. In figure 3, all of the drawings represent unstained cells as seen with dark contrast phase microscopy and correspond to some of the photomicrographs in figures 1 and 2. Drawings in figure 3, 1-c, 1-f

FIG 3 Camera lucida drawings of definite erythroblasts (normoblasts) shown by dark contrast phase microscopy in figures 1 and 2. Most of the organoids are mitochondria. Original magnification 2350 diameters, reduction about one-third

and 2-d show all of the organoids in the thin layer of cytoplasm between the flattened nucleus and the cover slip. Dark contrast was so striking in these preparations that a casual observer might readily believe the preparations had been stained with either Sudan black or iron hematoxylin. Note that structures in the cytoplasm are in general similar to those situated over the nuclear area. In figure 3, drawings 2-e and 2-f depict what is seen in optical sections through and beneath the nucleus. It was surprising to find cell contour changed with various levels. This three dimensional variation is not appreciated in dry smears fixed in methyl alcohol. The important thing derived from these observations was that distribution of organoids within the two thin layers of cytoplasm is neither uniform nor equal.

However, there does seem to be a general rule governing the distribution of these organoids in lymphoid cells. The cells in figure 4, A and B-1, represent two adjacent

FIG 4 Camera lucida drawings of definitive erythroblasts (normoblasts) as seen with dark contrast phase microscopy in three optical sections. Cells A and B¹ show distribution of mitochondria in layer of cytoplasm between cover slip and nucleus. Cells B² and B³ show optical sections at different levels. Diagram illustrates cross section of erythroblast suspended from cover slip in 10 per cent formalin. Arrangement and legends were made by M. D. Diedrich, Director of Medical Illustration, University of Buffalo.

cells in which the distribution of organoids in the same optical sections differed inversely. In other words, the layer of cytoplasm above the nucleus in cell A is like the layer beneath the nucleus in cell B with respect to the amount of organoids

An impression was gained, however, that perhaps more lymphoid cells had the majority of their organoids in the cytoplasm beneath the nucleus than above in coverslip preparations. Very likely the distribution of organoids depends upon such variables as degree of flattening, speed of the drying process and resultant thickness of the cytoplasmic layers. In an optical section through the nucleus, figure 3, B-2, one is again impressed by the appearance of the nucleolus. In figure 3, B-3, the optical section shows that layer contains about as many organoids as the higher level in cell A. The relative vertical sizes of these three levels were 2.5, 2.0 and 3.0 microns respectively. In other words, organoids are most numerous in the thicker layer of cytoplasm. It is very likely that the reason why the majority of cells have fewer organoids in the layer between the nucleus and the cover slip was due to the labile condition of the cytoplasm at the time the imprint or smear was made. Cytoplasm displaced from this position would tend to carry organoids around the edge of the flattening nucleus and distribute them in the thicker layer.

2. *Supravital Studies* Although phase microscopy makes it possible to see structures in unstained dry smears, the problem of identifying them and learning something of their nature remains. Hence, various dyes were used for supravital studies. The most successful of these was Janus green in dilutions of 1:20,000 and 1:40,000. Definitive erythroblasts (normoblasts) in these preparations were laden with green colored mitochondria corresponding in number, size, shape and distribution to most of the structures illustrated in figures 1-3. They were so numerous it seemed that little room remained for other organoids. This was particularly true of pronormoblasts and transitional cells between them and the mesenchyme. Ring-forms appeared as rods, ellipses or circles depending upon their orientation. The filaments were quite uniform. The number of mitochondria above and beneath nuclei was most impressive. So much so, that it is impossible to imagine how these cells could be smeared and dried without trapping many mitochondria in these locations. Practically all of these observations were made on the youngest cells and only slight consideration was given to the mitochondria in later stages of erythroblastic development. However, it was noted that the mitochondria tended to be more uniformly coccoid as maturation progressed. After one half hour, most mitochondria commenced to fade so that practically no green was visible by one hour after the preparation was made. However, in one sealed preparation kept at room temperature, the mitochondria remained colored for six hours.

Dahlia violet and neutral red brought out very few structures in preparations standing less than one hour. There was a slight indication that dahlia would tint some mitochondria. When the concentration of dahlia was increased to 1:10,000 a few dark solid spheres and crescents did take the stain rather intensely. These are probably portions of the Golgi element.⁴ Neutral red vacuoles did not appear in the definitive erythroblasts as readily as they did in the primitive ones. After livers had been kept in the dye solution for one hour there was a sporadic and sluggish formation of neutral red vacuoles and granules. They were more numerous and larger in preparations kept for five to six hours. Dornesco and Steopoe¹¹ reported a similar difficulty in staining fish erythrocytes. One particular advantage in using fetal livers for studying erythropoiesis is that terminal developmental stages of

primitive erythroblasts are present in the circulating blood. Hence, in either dry smears or supravital preparations it is possible to study early definitive erythroblasts (pronormoblasts) as well as primitive ones in the later stages of their development. The latter develop neutral red vacuoles fairly rapidly in preformed structures before the former show any signs of reacting to the dye. When neutral red does appear in young definitive erythroblasts it does not seem to involve preformed structures. According to Dustin¹⁰ this difference in the reaction of erythroblasts to neutral red is due not only to the presence of preformed vacuoles but to the condition of cytoplasmic nucleoproteins. In young erythroblasts the basophilia is stable but in those with considerable hemoglobin the basophilia is labile. For further consideration of this topic, see Dustin's discussion.¹⁰

3 *Sudan Black Preparations* In a previous study¹ it was shown that there was a good correlation between the distribution of mitochondria and the presence of lipid material. Furthermore, pictures obtained with Sudan black in primitive erythroblasts of the 11-day rat embryo corresponded very well to those of unstained cells seen with dark contrast phase microscopy. Hence, it was quite natural to expect that mitochondria in Sudan black preparations of erythroblasts in the 15 day embryonic liver might look like the cells in figures 3 and 4. Unfortunately, this was not the case. There was very little sudanophilic material in pronormoblasts of the second generation as compared with primitive erythroblasts from the 11 day yolk sac. Mitochondria appeared as very faint grey ring forms and filaments. In spite of this, it was possible to show that these organoids were distributed in the cytoplasm above and beneath the nucleus. If, as Lison and Baker claim,^{4, 16} Sudan black demonstrates the distribution of total lipid, then mitochondria in these two cell types differ markedly in this respect. As to whether or not the exposure of these mitochondria to vapors of strong oxidizing reagents is necessary to saturate the unsaturated lipids and change them from a nonstainable to stainable form as Ralph³ reported is not known at the present.

4 *Vitamin A* In a previous study¹ it was shown that the presence of vitamin A could be demonstrated in dry smears of embryonic blood and that it was localized in mitochondria. Similar studies were carried out on smears of the fetal liver. Vitamin A was present in the definitive erythroblasts (normoblasts) and in some of the polychromatic primitive erythroblasts. The reaction was fairly strong and could be localized in the ring forms as well as filaments.

5 *Permanent Mitochondrial Preparations* All of the evidence presented in the preceding sections indicates that most of the organoids in young definitive erythroblasts (pronormoblasts) are mitochondria. Additional evidence of a confirmatory nature was obtained in the aniline acid fuchsin preparations. Fuchsinophilic bodies—ring forms and filaments—were in the cytoplasm as well as over the nucleus. For the most part they were smaller than those in supravital preparations and unstained smears mounted in formalin. Very likely this was caused by the rigorous fixation and subsequent heat treatment.

6 *Separation of Mitochondria from Fresh Erythroblasts* Since most of the mitochondria in young definitive erythroblasts (pronormoblasts) are ring, elliptical or crescent shaped, it would be interesting to determine whether or not they maintain

their shape after being removed from erythroblasts. Three preliminary experiments, patterned after the method used by Hoerr¹⁷ for extracting mitochondria from adult guinea pig liver, have been carried out. Six 15 day fetal livers were dissected free from surrounding tissues and ground in a small mortar at room temperature. This material was then suspended in 3 cc. of 0.85 NaCl cooled to 0° C. and centrifuged at 500 r.p.m. for one-half hour. Both the supernatant and sediment were sampled and examined by dark contrast phase microscopy ($0.15\mu - \frac{1}{4}\lambda$). The supernatant contained many organoids and the sediment contained some intact erythroblasts and organoids. The supernatant was withdrawn and centrifuged at 2100 r.p.m. for one minute. A sample showed ring forms were present in top layer. The supernatant was withdrawn and centrifuged again at 3000 r.p.m. for fifteen minutes. The supernatant still contained a few ring forms but most of them were in the sediment. The small packed mass was broken up in 5 drops of 10 per cent formalin. Some of this was placed beneath a cover slip and sealed with vaseline for examination by dark contrast phase microscopy.

Since erythropoiesis is so conspicuous in the fetal liver and since ring form mitochondria are numerous in erythroblasts, the chances are that the isolated mitochondria came more from erythroblasts rather than hepatic epithelium. It seems to me the important thing to be gained from this observation is that mitochondria—ring forms in particular—behave as discrete structures and resist considerable mechanical force. Unfortunately, however, filaments did not survive this process of isolation.

7 *May-Grünwald-Giemsa Preparations* The observation that nuclei of various young definitive erythroblasts were sandwiched between two layers of cytoplasm containing many mitochondria quite naturally led to the question of what was their appearance in dry-fixed smears stained with standard hematologic dyes. Since it was known that light areas in basophilic cytoplasm represent negative images of underlying mitochondria,¹ it was felt that a somewhat similar picture might be obtained over the nuclear area. Before describing these recent observations, there are a few points which should be mentioned with respect to work previously done on human fetal livers.¹⁷ In both previous and present studies, the methods of preparing and staining dry imprints of fetal liver were identical. In 1935, my attention was focused almost exclusively on the chromatin—its size, shape, distribution and staining affinity.¹⁸ The same light areas which are about to be described and discussed were all considered as parachromatin—interchromatic nuclear spaces. My most extensive description was as follows. The parachromatin is faintly acidophilic producing a light pink tinge. However, in the case of promegaloblasts from pernicious anemia bone marrow the description was slightly more detailed.^{18, 19} It was that, There is quite a large amount of parachromatin which is in the form of curved areas. The small masses of chromatin which are separated by curved areas of parachromatin are uniformly distributed throughout the nucleus.

An examination of the light areas in the basophilic cytoplasm showed that there was considerable variation in their size, shape and distribution. This is illustrated in figure 5a, which represents a transitional stage between the mesenchyme and

pronormoblast In the area between the nuclear membrane and the arrow there are negative images of mitochondria having the shape of filaments, short rods, spheres and ring forms No forms are present in this area for which counterparts cannot be discovered over the nuclear area This is also true for the reticular lymphocyte

FIG 5 Photomicrographs of definitive erythroblasts (normoblasts) as seen in dry smears stained with May-Grünwald-Giemsa Magnification 1850 diameters Unlabeled cell is a polychromatophilic primitive erythroblast for comparison All others are young definitive erythroblasts (normoblasts) from 15 day embryonic rat liver Arrows point to light areas—negative images of mitochondria—discussed in text Photomicrographs were made by M D Diedrich

illustrated by Sundberg and Downey²⁰ in their figure 9 The difficulty, however, lies in the fact that contrast between the negative images and their surroundings in this location is not as great as it is in the basophilic cytoplasm that lies beyond the nuclear membrane This unquestionably is one of the reasons why hematolo-

gists have never or rarely doubted that all of the so-called parachromatic areas were entirely of nuclear origin. The other reason, of course, is that hematologists did not know freshly dried blood smears preserve cytoplasmic detail to an extraordinary degree.¹

If some of the so-called parachromatic areas are of cytoplasmic origin, then it should be possible to find cells with negative images of mitochondria straddling the nuclear membrane. The cell in figure 5b is of interest because a filamentous light area extends from the cytoplasm beyond the flattened nucleus, across the nuclear membrane and continues over the nuclear area. In this cell, ring forms were also trapped between the nucleoli and cover slip. In figure 5c the arrow points to a cytoplasmic area in a pronormoblast which contains quite a few ring and elliptical forms. Similar forms, negative images, may be seen resting on the edge of the nuclear membrane while others are over the nuclear area. If these light areas are described with respect to the chromatin, it may indeed be said that there is sharp demarcation between them. This is a characteristic which for many years has been claimed for young erythroblasts and other myeloid cells. Figures 5d and 5e represent either late pronormoblasts or early basophilic normoblasts. In figure 5d, opposite the pointer, there is a filamentous light area which extends from the cytoplasm that lies beyond the nuclear membrane and continues over the nuclear area. In figure 5e, a similar condition exists but instead of one there are three such areas. Similar negative images, presumably of mitochondria, are shown in figure 10 of the article by Sundberg and Downey.²⁰

These observations indicate that not all of the so-called parachromatic areas in lymphoid cells studied thus far are of nuclear origin. Many of these light areas—differing in size, shape and distribution—represent the negative images of mitochondria which have been impressed into the nucleus by drying and fixation. In other words, the nuclei of these cells have at least two entirely different substances which are light staining: one the oxychromatin and the other negative images of organoids.

In a previous section (B 1) it was shown that the distribution of organoids, mitochondria for the most part, varied in the layers of cytoplasm on either side of nuclei of cells in dry smears mounted in 10 per cent formalin. When dry smears are stained with one of the Romanowsky dyes, methyl alcohol fixation produces some shrinkage, and mitochondria above and below the nucleus are impressed into it. Hence, in a critical morphologic examination, it might make a difference whether preparations are on slides or cover slips. In the former, a free and slightly convex surface is examined first, whereas in the latter it is the flattened surface in contact with the glass which is examined first. This might influence the appearance of optical sections just beneath these levels. In order to study both sides of these erythroblasts, small square cover slip preparations were mounted in clarite on larger 24 × 60 mm cover slips. Negative images of mitochondria over the nuclear area were studied and sketched to show their distribution. In some cells, which were transitions between mesenchyme and pronormoblasts, it was possible to show that the nuclear area had four distinct regions depending upon the shape and distribution of the mitochondria as represented by negative images. This gave the chromatin a differ-

ent appearance in each region. In some, the filamentous and short rodlike mitochondria made the chromatin appear as if it was broken up by crevices (The drawing of a hematopoietic reticular cell, figure 7 in an article by Sundberg,²¹ has a similar pattern.) In others, the ring and elliptical forms gave the chromatin a chain or droplet effect. When ring forms were in a horizontal position it was possible to see chromatin through their central area. If these "doughnuts" were in basophilic cytoplasm, then their centers would appear blue. Quite naturally, if it were not known that dry smears preserve organoids which are impressed into the nucleus and appear as negative images, then it would be justifiable to describe these several chromatin patterns within a single cell as being intrinsically nuclear. Sundberg and Downey²⁰ have described myeloblasts and reticular lymphocytes with three or more types of chromatin arrangement within a single cell.

By turning these preparations over, the other sides of cells were examined. Differences between the two sides were so slight that they could not be ascertained without knowing which side of the cell was being examined first. The reason for this is very likely that the shrinkage which accompanies methyl alcohol fixation tends to decrease distances between organoids in the two layers of cytoplasm on either side of the nucleus. Hence, optical sections through the nucleus would include nearly all organoids impressed into the nucleus. It was felt, however, that negative images of mitochondria impressed into the nucleus on the flattened surface adjacent to the cover slip were perhaps better defined.

8 *Comment* Although all of the foregoing observations were made on erythroblasts from rat fetal livers, enough human fetal liver material was examined to show that in general the same conditions obtained. Lymphoid cells from adult rat lymph nodes were studied in supravital and dry smear preparations by brightfield microscopy, and in supravital and unstained 10 per cent formalin preparations by phase microscopy.

DISCUSSION

Prior to 1900 all lymphoid cells were grouped together, since most hematologists were unable to find any differences between those of the marrow and lymphocytes in normal circulating blood.²² Naegeli²³ was the first hematologist to recognize and describe a characteristic chromatin arrangement in marrow cells. This was a uniform netlike structure present in small as well as large myeloblasts. And, as Downey²² pointed out, it is the most permanent and reliable characteristic of the myeloblast which has survived until the present. Accurate descriptive terminology was more or less lacking in the field of morphologic hematology until Pappenheim²⁴ set a standard which is still accepted by many hematologists. He defined spongioplasm, paraplasm (hyaloplasm), parachromatin (karyoplastin), and chromatin with respect to their appearance in dry smears. The first three were grouped together and called plastin substances because they differed from chromatin by never taking up methyl green. Pappenheim made the keen observation, which almost seemed to be a law, that tinctorial reactions of the paraplasm and parachromatin paralleled each other. When this was applied to erythroblasts, he maintained that since staining of paraplasmatic hemoglobin paralleled that of the parachromatin,

it suggested an intimate genetic relationship because the former grew and changed tinctorially at the expense of the latter. He concluded that parachromatin or the interchromatic nuclear spaces were not produced merely by transillumination of plasmatic hemoglobin of the plasmatic cell circumference (i.e., cytoplasm above and beneath the nucleus in a dry smear), because they were also found in the torn out and displaced erythroblastic nuclei. Although Pappenheim may have been in error regarding the exact relationship between light areas in the cytoplasm and nucleus, he at least doubted momentarily that parachromatin was entirely of nuclear origin.

Pappenheim, Schridde, Naegeli, Ferrata, Downey and others, including the present author, have repeatedly emphasized that dry-fixed smears bring out the finer structural details of the nucleus which are important for the identification and interpretation of lymphoid cells which have not developed specific cytoplasmic characteristics. It has been generally accepted by all of these men that descriptions of nuclear detail, pattern, or structure have referred to intrinsic characteristics of flattened nuclei. To be sure, specific and azurophilic granules, and Auer bodies may have been either over or under a given nucleus, but these presented no problem because they were visible and readily recognized as such. Some hematologists must have pondered the fate of the cytoplasm in a more or less spherical cell which was subsequently flattened and dried. Likewise, some hematologists must have wondered what happened to the organoids when cells were smeared and dried. These questions quite naturally had to remain unanswered until the development of proper cytologic, cytochemical and optical techniques paved the way for their exploration.¹ Even before these techniques were utilized, Dr. E. R. Hayes of our department suggested that a possible solution might be to make smears on celloidin or some plastic substance and section them.

The present study is the natural outgrowth of a problem originally undertaken to determine the nature of the so-called hyaloplasm.¹ Investigation of various lymphoid cells with leptochromatic nuclei has shown that the thin layers of cytoplasm on either side of a flattened nucleus contain organoids in variable quantities. These were impressed into the intervening nuclear material during the drying and fixing processes in making a smear or imprint of hematopoietic tissue. When stained with Romanowsky dyes, the organoids—chiefly mitochondria—appeared as negative images over the nuclear area, just as they did in the basophilic cytoplasm. Unfortunately, it was impossible to separate readily all light areas of cytoplasmic origin within the nuclear area from those produced by intrinsic properties of the nucleus—oxychromatin in particular. All light staining material within the nuclear area, as seen in dry smears, has been described previously as either parachromatin¹⁸⁻²⁴ or karyoplasm.²¹⁻²⁵ Since the evidence derived by studying blood cells with several techniques indicates that cytoplasmic organoids may also contribute to the production of these light areas, it seems necessary to define the term nuclear structure.

Fundamentally, the morphologic basis for nuclear structure during interphase should include the nuclear membrane, chromatin reticulum, linin, nucleoli, and karyoplasm or nuclear juice. It should be an interrelation of the parts as dominated

by the general character of the whole. For practical purposes, the distribution of chromatin may be determined by using suitable basic dyes. However, in order to ascertain the true distribution of chromatin, the Feulgen reaction for desoxyribose nucleic acid must be used to exclude the possibility of other nucleic acids taking on basic dyes. Recent studies by Mirsky and Ris²⁶ indicate there may be a definite chemical difference between basichromatin and oxychromatin. The proposed definition of nuclear structure would apply to cells seen in histologic sections, optical sections of moist fixed smears, living cells and dry fixed cells mounted in aqueous media for phase microscopy.

This definition would not apply to lymphoid cells in the present study because the appearance of their nuclei was altered by the presence of organoids—chiefly mitochondria—contained in the thin layers of cytoplasm on either side of flattened nuclei as seen in dry smears. These structures appeared as negative images impressed into both sides of flattened nuclei. The extent of this alteration depends upon the type, amount and distribution of organoids present at that particular time. The picture thus presented is a pattern in the nuclear area produced by flattening the nucleus between overlaying and underlying organoids within thin layers of cytoplasm. This pattern is an arrangement of the parts that suggest a design. Therefore, unless one is absolutely certain that the nucleus has not been so influenced, it would be more appropriate to speak of the nuclear pattern of cells as seen in dry smears rather than the nuclear structure. Of course, the nuclei of all cells will not be so influenced by organoids because as they mature, as in the case of erythroblasts, there is a gradual diminution of cytoplasmic constituents. Hence, when an orthochromatic normoblast is examined the chances are that its nucleus was flattened between two layers of cytoplasm containing very few or no organoids to influence the parachromatic pattern. There is another aspect of this problem which has not been explored, namely, that slight differences in nuclear structure as seen in sectioned material may become accentuated when these more or less spherical bodies are flattened. Nuclear pattern must include intranuclear as well as extranuclear or cytoplasmic components. This tends to offset Maximow's criticism²⁷ that, "The minute differences of the nuclear structure, seen only in dry smears, might very well depend merely on the differences of external conditions, encountered by the cell in the various places and the various stages of development of the body."

Although it is necessary to have phase equipment to duplicate the present results, such equipment is not essential to check in general some of them. For example, by using either oblique lighting, or decreasing the condenser diaphragm, or a combination of these, or by dark field illumination, it is possible to determine that certain organoids are above the nucleus in mounted unstained dry smears. These methods, unfortunately, tell us nothing regarding finer details of these structures. Furthermore, if inquisitive hematologists had been really interested in determining the fate of mitochondria in dry smears, they could have arrived at the same conclusions through correlative studies of supravital material, Schridde and Freifeld preparations (methods outlined in Naegeli²⁸) and dry smears. For example, in the recent study¹ on the relation of mitochondria to the so-called hyaloplasm the major conclusions were drawn from dry smear, supravital, aniline acid fuchsin,

Sudan black and antimony trichloride preparations before phase microscopy was used. The latter, however, clinched the argument. It may be shown eventually that the dry smear method preserves mitochondria better than any of the accepted technics. At least it may now be said that good dry smears preserve mitochondria in lymphoid cells with an unexpected degree of accuracy.

It should not be difficult for hemopathologists and clinical hematologists to think also in terms of cytoplasmic activity when interpreting various cellular responses, because undoubtedly a number of differences in nuclear pattern which they have studied have been due in some measure to organoids above and beneath flattened nuclei. In other words, part of their interpretations of altered cellular functional activity probably have been due to cytoplasmic conditions superimposed on nuclear ones. Since cytologists have shown there is a greater correlation between cellular function and the cytoplasm than between it and the nucleus, it means that by studying nuclear patterns in lymphoid cells we have a reflection of the nuclear as well as cytoplasmic alterations due to functional or metabolic activity.⁶ We have been studying cytoplasmic alterations unknowingly for a long time (fifteen years in my case) and have inadvertently credited the functional activity of lymphoid blood cells almost entirely to nuclear metabolism with little or no credit to the basophilic cytoplasm and its negative images of underlying mitochondria. This interpretation in no way detracts from the role the nucleus has as a primary center of control in cellular metabolism and the importance of its organization.²⁹

The results of the present study indicate that the dry smear method of studying immature blood cells produces nuclear patterns formed by the sum total of nuclear and cytoplasmic alterations. It seems to furnish a more sensitive indication of what a cell is doing than any other single known technic. For years, the neo-unitarians have, in many instances, more or less bridged the gap between the unitarians and the extreme polyphyletists (supravitalists). The reason is now more apparent than ever before. The unitarians or monophyletists relied chiefly on the use of tissue sections, hence they studied nuclear structure. (In this connection, it should be noted that Mirsky and Ris³⁰ have recently isolated chromosomes from interphase nuclei of fish erythrocytes and lymphocytes of calf thymus.) The supravitalists have relied primarily upon alterations of the cytoplasm and very little upon nuclear structure. There is some doubt as to whether or not they even studied all of the structures in certain cells.^{1, 11} Certain supravital dyes like pinacyanol stain the nucleus as well as the mitochondria but nuclear patterns are not produced because mitochondria are not impressed into the nucleus. The neo-unitarians and dualists have been observing and describing differences due both to the nucleus and cytoplasm, especially in lymphoid cells. It is to their credit to have recognized that something was producing differences in nuclear pattern, even though it evaded detection until new technics clarified the contributing role of the cytoplasm. The present studies offer an explanation why Downey,²² and later Sundberg and Downey,¹⁸ concluded that the dry smear or imprint method revealed minute but significant differences which are lost through the use of other techniques. But it must be remembered that there exists an extreme variability of the morphological characteristics of any one cell type.²⁰ As a consequence we must pay more atten-

tion to nuclear pattern than we have in the past and we must give even more consideration to the range of variation of these patterns Pappenheim³¹ also recognized the importance of the latter

The concept developed in this paper that nuclear pattern is a reflection of nuclear and cytoplasmic alterations should be applied to other cells in other conditions Klemperer³² mentioned that "Every discovery of a structural detail in the cell arouses the question as to its functional significance" He also deplored the fact that cytologic investigations on mitochondria require a highly developed technic The present approach may be useful in studying certain aspects of cellular pathology It would be instructive to determine how much of the nuclear pattern of immature leukemic cells is due to cytoplasmic constituents In this connection, it should be pointed out that Lewis³³ suggested the derivation of malignant cells from normal ones might possibly be due to cytoplasmic alteration Later, Potter³⁴ studied—extracellularly—certain enzymes associated with cytoplasmic components and as result advanced his enzyme-virus theory of cancer Shortly afterwards, Woods and DuBuy reported that virus diseases, variegational diseases and cancer in plants may be related through changes in mitochondrial equilibria Although metastatic tumor cells in hematopoietic tissues might prove to be suitable material for studying the role of the cytoplasm in the production of nuclear pattern, there may be some difficulty in adapting these methods to exfoliated cells from cancerous tissues ³⁶ Dr Raymond Kibler³⁷ from our laboratory has already extended many of these studies to myeloma cells with considerable success Sundberg²¹ reported that "The uniformity of nuclear structure in both myeloblasts and lymphoblasts might well be the result of repeated mitoses without subsequent differentiation" Since mitochondria are abundant in dividing cells, future studies may reveal that these organoids are responsible for that uniform nuclear pattern This may also explain why hematologists have observed that the demarcation between the chromatin and parachromatin becomes more distinct in immature lymphocytes The role of the lymphocyte in acute inflammation³⁸ should be reinvestigated It is very likely that the increased hyaloplasm is not due to inhibition or cellular edema, but rather to an increase in the number of mitochondria as a result of accelerated functional activity It would also be interesting to reconstruct the changes in lymphocyte nuclei as they transform to macrophages and determine the role played by the cytoplasm ³⁸ And finally, dry smears of tissue cultures may be suitable for similar analyses ³⁹

SUMMARY

- 1 Lymphoid cells from rat and human fetal livers and adult rat lymph nodes were studied by means of various cytologic, cytochemical and optical technics
- 2 Freshly dried smears preserve cytoplasmic detail with an extraordinary degree of accuracy
- 3 Mitochondria, both numerous and pleomorphic, are preserved in the cytoplasm which lies beyond the nuclear membrane as well as in the thin layers of cytoplasm above and beneath the nucleus
- 4 In dry-fixed preparations stained with Romanowsky dyes, mitochondria

appear as negative images (light areas) in basophilic cytoplasm. These negative images within the nuclear area contribute to the formation of what hematologists in the past have described as parachromatin.

5 The dry smear method of studying lymphoid blood cells produces nuclear patterns formed by the sum total of nuclear and cytoplasmic alterations which reflect functional activity.

6 The meaning of the terms nuclear structure and nuclear pattern have been contrasted.

ADDENDUM

Dr. Arnold Lazarow recently called my attention to the fact that other cytoplasmic constituents have been preserved in air dried smears of hepatic tissue. Paul Ehrlich (*Ztschr f klin Med* 6 43, 1883) anticipated by this method the results found later by the more elaborate freezing-drying technique. Ehrlich observed the homogeneous distribution of glycogen in liver cells.

THE BONE MARROW ON STERNAL ASPIRATION IN MULTIPLE MYELOMA*

By EDWIN D. BAYRD, M.D.

INTRODUCTION

THIS STUDY of the bone marrow on sternal aspiration in multiple myeloma is concerned primarily with three main points (1) the type of cell or cells involved in the production of the disease, (2) the origin of this cell or these cells, and (3) cytologic criteria for the degree of malignancy.

As will be noted more fully later on, there seems to be no point of agreement on the first two aspects of this subject and almost no information whatsoever on the third.

An attempt will be made herein to elucidate all three of these issues insofar as a study of the available literature and material at hand permits.

All satisfactory sternal marrow smears available through February, 1947, were reviewed for cell type and indications of origin. These numbered seventy-one altogether. Fifty-one cases were studied completely with differential counts, as noted subsequently, and with attention to all morphologic detail. These observations were used in an attempt to correlate cytologic findings with clinical findings. Forty-three cases had been seen long enough ago to be included in the follow-up study for indications of degree of malignancy. This last group includes all of those cases seen at the Mayo Clinic through December, 1945.

METHOD

The technics of sternal aspiration used have been various modifications of the Arinkin method¹ (using a Klima and Rosegger needle²) and have been fully described previously.³⁻⁶ The present method employed is that used by Schleicher.³⁻⁵⁻⁶

One to 2 cc. of the marrow material was withdrawn with a dry sterile syringe from the gladiolus at the level of the second interspace after inserting the tip of guarded needle and stylet 1 to 2 mm. beneath the inner table of the cortex. In addition to the marrow blood withdrawn, small elements (units) of bone marrow are apparently withdrawn intact. The whole is placed in a paraffin-lined heparinized glass tube. The use of these small units permits fixed tissue technics to be employed on the same bone marrow from which volumetric studies and smears are made.

Smears alone were available for review in the large majority of instances but in the few cases in which tissue was also available and of additional interest this fact is indicated. In addition to a general description of the sternal marrow smears that were made on each case after a period of study, differential counts of 200 marrow

cells were made. Further "differential counts" were conducted on 100 "myeloma cells" in each case in an attempt to develop an objective method for determining the degree of anaplasia or immaturity.

A small, 200 cell differential count was considered to be adequate for this study, (1) because a larger 1,000 cell count run as a pilot showed less than a 3 per cent variation in the predominant cells present, (2) because the limits of normal are so wide^{4, 7} that only gross changes are significant, and (3) because quantitative relationships in these marrows are of secondary importance. The number of nucleated erythrocytes per 100 myeloid cells was noted. The "myeloma" cells were classified as old if the nuclear chromatin was fairly compact and the nucleus small (usually eccentric), tending to resemble the ordinary plasma cells, whether or not a nucleolus was present, although this was noted.

The intermediate stage cell, the type most often seen in multiple myeloma, usually had one or more large nucleoli and a vesicular, finer stranded nucleus with or without chromatin "dots" (small isolated, denser areas of chromatin). There was, in this group, less tendency toward eccentricity of the nucleus than in the old cells. The young or immature forms were those with a large nucleus, with a very fine chromatin skein, with or without nucleoli such as seen in the stem cell or the reticulo-endothelial cell. Here the nucleus showed the least tendency toward eccentricity. This division proved to be a workable, though, as might be anticipated, not an infallible one.

HISTORICAL REVIEW

The significant clinical feature and gross morphologic aspects of the disease now widely known as "multiple myeloma" were developed largely during the latter half of the nineteenth century from the time of Macintyre,⁸ Watson, Bence Jones⁹ and Dalrymple¹⁰ in 1848 to 1850 to that of Wright¹¹ in 1900. Macintyre described a case, appropriately enough of a man, 45 years old, who was seen in consultation with Dr. Watson, in whose urine Bence Jones noted some abnormal protein matter and on whom Dalrymple reported the microscopic findings in two affected ribs. Subsequently, Rustizky,¹² Kahler¹³ and Bozzolo¹⁴ added coherence to the clinicopathologic picture of the disease and stimulated the reporting of more cases.

Until 1900, when Wright¹¹ published the studies he had made on a case of multiple myeloma that had come to his attention in February, 1898, no one had linked the offending marrow elements to the plasma cell. Shortly thereafter, however, Christian¹⁵ reported on 6 cases, all with this characteristic finding, although he later stated¹⁶ that he considered the myeloma cell to vary within the limits of plasma cell on one side and myelocyte on the other. Since that time, 75 to 80 per cent of reported cases have been of the plasmocytic type. It was during these formative years and the next two decades that most of our concepts of etiology, cell type and histogenesis were laid down. This was done in the main by pathologists utilizing fixed tissue sections. Subsequently, some of the other more bizarre manifestations of the disease were emphasized, such as hyperproteinemia,¹⁷⁻²¹ rouleau formation,^{4, 22-26} myeloma cells in the peripheral blood^{23, 24, 27-31} and associated amyloidosis.^{19, 25, 35} Two of the most complete reviews of the problem

to date include those of Geschickter and Copeland,⁷⁶ and Atkinson.¹⁹ The relationship of the diffuse multiple myeloma to the solitary myeloma, intraosseous and extraosseous, and 'plasma cell leukemia' has been discussed by many authors, a few of whom are noted.^{27-31, 33-35} In 1929, Arinkin¹ introduced his method for bone marrow aspiration and since then more attention¹⁻³⁹⁻⁴³ has been directed toward this technic as a method of diagnosis and means of studying the histopathologic characteristics of this disease.

COMMENT ON THE LITERATURE

A. THE TYPE OF MYELOMA

It has been widely held since the concept of multiple myeloma was first formulated that several, if not all, types of marrow cells were involved in the production of the specific lesion. There were thus erythroblastic,⁴⁴⁻⁴⁶ lymphocytic,⁴⁷⁻⁴⁸ megakaryoblastic,^{41-49, 50} myeloblastic,^{45, 46, 48, 51, 52} and myelocytic,^{79, 44, 46, 48-53} as well as plasmacytic, 'lipoblastic'⁵⁴ and osteoblastic types.^{53, 54} Of the current texts in pathology or clinical pathology this opinion finds support among Bell,⁵⁵ Wood,⁵⁶ Moore,⁵⁷ MacCallum,⁵⁸ Oertel,⁵⁹ Gradwohl,⁶⁰ and Kolmer and Boerner⁶¹ and further acceptance by other authors.^{16, 37, 62-77} Boyd⁷⁸ seems to support those whose contention it is that all types are but a variation of one cell type when he remarks (having previously listed the usually accepted types) that "on the other hand it is equally possible, indeed probable, that the apparent variety is merely due to anaplastic changes in one fundamental cell type."

By the time Wright¹¹ made his first observations incriminating the plasma cell in 1900, the following histopathologic diagnoses had been made on the lesions of cases accepted as multiple myeloma: lymphosarcoma, myelogenous pseudoleukemia, lymphadenoma, hyperplasia of marrow, vascular endothelioma, sarcoma, small round cells and lymphoid cells. In 1904, Weber¹⁷ reviewed the literature (38 acceptable cases) and reported one of his own. This case he classified as a "myelocytic" myeloma. He also recorded a second previously reported case, which he designated as 'lymphocytic' although he mentioned the presence of more than the usual amount of cytoplasm and occasionally eccentrically placed nuclei.

In 1910, Williams and associates⁷⁹⁻⁸⁰ reported a case of plasmacytic myeloma and also reviewed the slides and tissue of a case reported by Moffatt⁸¹ in 1905 as lymphocytic. It was their expressed opinion that this, too, was plasmacytic. And even as early as that time they observed that "this suggests that further research will show that the differences in the type of cell are more apparent than real, and are the result of differences in fixation, staining and description, or perhaps in degree of anaplasia." Shennan,⁵² in 1913, also, in a good discussion of the early literature, reported 3 cases, the second of which he regarded as myelocytic, the other two probably being plasmacytic. At the same time he presented a classification which included 'true myelocytes, premyelocytes or myeloblasts, lymphocytes, plasma cells and megaloblasts (erythroblastoma)'. However, it is interesting to see that though Shennan outlined a rather inclusive classification he did express some doubt that such a wide variety of types exists. "It is questionable

whether all the different varieties of myeloma described in the literature of the subject can be clearly differentiated from each other. Possibly the apparent differences are due to the variability of one cell type."

In 1916, Vance⁴⁶ reported a case which he placed somewhere between an erythroblastoma and a myelocytoma. He listed ten authors who had observed myeloblastomas, eight authors who had reported lymphocytomas, six who had noted myelocytomas, Ribbert's⁸² erythroblastoma, and several authors who had described plasmacytomas.

Wallgren,⁸³ in 1920, in a widely quoted review of the problem, expressed the opinion that a lymphocytic type does not exist, that newer methods of staining have done away with it, and that all myelomas are made up of cells of the same fundamental type which may, however, show certain varying stages of development, differentiation or degeneration. In 1928, Geschickter and Copeland³⁶ summarized the findings on 412 cases of proved multiple myeloma from the literature and reported on their findings in 13 of their own cases. They had this to say about myeloblastic and myelocytic types:

As for the so-called myeloblastic or myelocytic type of myeloma, we have repeatedly observed that concerning the same section two authorities will differ between these two terms. Ewing, in cases 8 and 11 in our series, used the term myelocytic or myeloblastic, while Bloodgood used the term plasma cell type. In running through a series of 12 proved cases in rapid succession, one finds that these 2 cases do not stand out especially as atypical and fit in well with the so-called plasma cell type, although superficially, the nuclei do not appear to be as typically spoke-like in arrangement. Many authors, in describing such cells in cases of multiple myeloma are uncertain whether to class these cells in the plasma or myelocytic series, and some of these authors have thought that the apparent difference was due to fixing or staining methods.

In some cases the differentiation was made on the basis of the oxidase reaction, and in other cases on the Unna-Pappenheim reaction for plasma cells. While the differentiation can thus be made in some cases, often it cannot be made either by oxidase reaction or by Unna-Pappenheim stain.

Wintrobe,⁸⁴ while noting that the "literature refers to myelomas of various types: myeloblastic, lymphoblastic, lymphocytic, myelocytic, erythroblastic and even hemocytoblastic and megakaryoblastic," said, "Plasma cell myeloma is the most common designation. There is a good reason to doubt the identification of the cells in many of the reported cases. Even many of those who have referred to plasma cells have admitted that those were atypical. Recent studies which have been aided greatly by the possibility of obtaining the tumor cells by sternal puncture, indicate that the myeloma cell is a peculiar form differing from any other cell type."

Cases reported in which tissue studies were responsible for diagnosis. Wood, Quinlan and Merrill⁸⁵ reported a case of multiple myeloma in which the patient was a boy 19 years old. Tissue obtained for biopsy was submitted to four pathologists for their opinion because of the infrequency with which this disease occurs in the first two decades of life. Wood, Warren, and MacMahon⁸⁵ expressed the opinion that this was a pleomorphic or atypical plasma cell myeloma, while Geschickter³ stated that it was of the 'primitive myelocytic series.' Donhauser and de Rouville⁸⁶ in reporting four cases of multiple myeloma noted that two were of the

plasma cell variety and that one was lymphocytic, while the other was myelocytic. This last was felt by Parker⁵⁶ to be Hodgkin's disease.

The foregoing 33 cases (table 1), reported since Wright made his observations on the plasma cell character of this tumor, are cases in which the histopathologic diagnosis is other than of the plasma cell type. It should be emphasized that in all of these cases the diagnosis was based on the examination of tissue sections. It will

also have been noted that great difficulty frequently attends the classification of these cells cytologically from tissue alone and that competent pathologists may differ widely in their opinions of the same tissue. And this takes no cognizance whatsoever of those cases in which a diagnosis of other than myeloma entirely was made erroneously, as has undoubtedly occurred in some instances.

Cases reported in which diagnosis was based on sternal aspirations. The technic of sternal aspiration is of relatively recent origin, yet, even so, enough cases of mul-

multiple myeloma have been diagnosed by this method to make a brief survey of available reports of interest (table 2)

Varadi¹³ reported on 7 cases, 5 of which were considered to be typical plasma cell forms, the other 2 being myeloblastic. The illustrations suggest that they might also be more anaplastic, younger varieties of the myeloma plasma cell.

Of the 6 cases in which Fleischhacker and Klima¹² obtained sternal aspiration material, five were classified as plasma cell types and one as [sic] 'Stammzellen myeloma?'. The question mark is theirs.

Rosenthal and Vogel¹⁰ reported on 13 cases, of which all but one were of the plasma-cell type. The exception, case 13, was called myelocytic, although 3 per cent of plasma cells were present in the marrow on two sternal aspirations. Two plasma cells pictured had three nuclei apiece and were vacuolated. In this case, three questions may be raised: (1) was this really leukemia with moderately increased plasma cells or (2) was this really multiple myeloma with a severe leukemoid reaction and, if so, would still another sternal aspiration (two were done) have shown a different spread of cells with more 'myeloma plasma cells,' and (3) would a diagnosis of multiple myeloma be justified in the complete absence of the 'myeloma plasma cells'? In the author's opinion the mere fact of a cell's preponderance does not establish a cell type.

Weissenbach and Lièvre,¹¹⁵ in the 5 cases which they described, found 3 to be 'histiocytoid' in type, and 2 plasma cell-like, again their description of the 'histiocytoid' cells, 'with eccentric nuclei, nucleoli, basophilic cytoplasm and frequently vacuolated,' prompts the speculation that these cells were merely the unrecognized, more anaplastic forms of the "plasma cell."

Erf and Herbut⁴⁰⁻⁴¹ reported 7 cases of multiple myeloma. 4 were of the plasma cell type, 1 was designated as lipoblastic, 1 megakaryocytoid and 1 myelocytic. The myelocytic patient had osteolytic bone lesions alone to suggest multiple myeloma, whereas her age, sex, hepatosplenomegaly, petechiae, marrow (10 per cent myeloblasts) and blood (6 to 15 per cent myelocytes) certainly point strongly to a diagnosis of leukemia. In this instance, then, a leukopenic leukemia is scarcely excluded. The sternal marrow in the case reported as megakaryocytoid disclosed many typical single or double nucleated plasma cells. 'It was because of the "many transitions from these to giant cells with as many as 22 nuclei" that it was considered to be megakaryocytoid. The mere hypernucleation of the plasma cells here would seem dubious justification for such a conclusion and certainly the absence of the "many typical single or double nucleated plasma cells" would have made the diagnosis of multiple myeloma itself suspect. The third unusual case involved a man forty-one years old who had bone tumors and anemia and died after a brief illness. No Bence Jones proteinuria was noted and his serum proteins were low. The sternal aspiration examination suggested to the authors a likeness to marrow fat cells though reference was made twice to "many cells that closely resemble plasma cells." It is not clear on just what ground—the presence of bone tumors, lipoblasts in the marrow, the resemblance of marrow cells to plasma cells or a combination of these—the diagnosis of multiple myeloma was made in this case.

If on the first two grounds alone, the evidence would seem rather tenuous, if on the third, then the myeloma could scarcely be other than a plasma cell type

Reviewing carefully, then, the 10 cases noted in which other than a plasma cell type was reported, in the light of the present study as will be subsequently noted, it is seen that one is probably a case of leukemia (Erf and Herbut's⁴⁰ case 5), one is doubtfully multiple myeloma (Herbut's and Erf's⁴¹ case 6), one (Rosenthal and Vogel's³⁹ case 13) plasma cell myeloma with a leukemoid reaction versus myelogenous leukemia or myelocytoma," and a fourth (Herbut and Erf's case⁴¹ 7) probably a plasma cell type, though not so reported. The other 6 are all reported as immature types, 1 with excess plasma cells, 3 with a description that fits well the more anaplastic plasma cell and another with illustrations which, if accurate, depict 'plasmablasts' as frequently seen in this series of sternal marrow examinations

Haden and Rumsey,⁶⁸ in 1940, reported on 16 cases in which sternal aspirations had been done. Individual cases were not reported as such, and hence will not be considered further here

The difficulties inherent in the establishment of a cytologic diagnosis from tissue sections are evident and are emphasized by the experience of Geschickter and Copeland³⁶, Wood, Quinlan and Merrill,⁸⁶ and Ulrich.³⁷ This point gains added weight by the observation of Erf and Herbut's⁴⁰ case 4 which was designated as myelocytic from sections, although the sternal marrow clearly demonstrated that these were plasma cells. Scott and associates¹³⁴ noted that "plasmoblasts" are not easily distinguished by routine staining methods from any early form of the myeloid or erythrocytic series and that this is probably the cause of many of the errors made by the early workers in interpreting them as myeloblasts and erythroblasts. They also pointed out the unreliability of "specific" plasma cell stains and the oxidase reaction in determining cell type in this disease (as have numerous authors) because of the variability of the cell to any of these tests

Churg and Gordon¹⁸⁰ in the same vein stated that "many cases [of multiple myeloma] have been reported in which the predominant cell was thought to resemble not the plasma cell but the myeloblast. This was true of many elements in our own material. If these cells had predominated, the case might have been called by some an instance of myeloblastic myeloma. However, all transitional forms between these and other cells resembling plasma cells were present. This statement is true in other reported instances. Apparently, many of the so-called myeloblastic cells are variants, perhaps younger forms of the typical cell of multiple myeloma. It seems logical, therefore, to group all the cells under one term, myeloma cell." ¹³⁵

Doan¹³⁶ said: "A diffuse hyperplasia of cells more or less characteristic of the so-called plasma type make up the new growth. The cells may show differing degrees of maturity. The plasmablast may be sharply differentiated from the myeloblast, lymphoblast and monoblast by the characteristic filamentous mitochondria (Doan and Lewenstein, 1936, unpublished data)." And Jones¹³⁷ noted that others have reported myelomas composed of myeloblasts, lymphoblasts, lymphocytes and erythroblasts. Apparently this discrepancy is due to the un-

certain identification of these cells in section material Fleischhacker and Klima point out that since the advocacy of sternal puncture the cells encountered in myelomas have been predominantly of the plasma cell type. Since these multiple myeloma cells may be immature they may present a picture similar to myeloblasts."

B HISTOGENESIS

Many of the early conceptions of the immediate precursor of the myeloma cell depended on the accepted concept of multiple cell types and many authors have stated that a myeloma cell might arise from a lymphocyte,^{29 48 62 69 86 92} lymphoblast,^{45 48 56} myeloblast^{45 46 48 51 52 63 66 69} or erythroblast.^{78 41 45 48 63 66 69} In addition, it has been conceived that the osteoblast⁵¹ or osteoclast⁵³ might be the progenitor of the myeloma cell. This hypothesis has no adherents today and fails entirely to consider extrasosseous plasma cell lesions which may clearly precede multiple osseous spread.

The conception of the relationship of myeloma to the erythroblast has developed on very frail evidence, has failed of corroboration with sternal marrow aspiration, and may be dismissed also without further discussion (even though Meyer and associates⁷⁸ noted a confusing similarity between plasma cells and nucleated erythrocytes in their reported case of 'plasma cell leukemia'). Since the origin of the plasma cell from the lymphocyte has long been authoritatively advocated, it is not necessary to believe that lymphocytic multiple myeloma exists in order to postulate a lymphocytic derivation for it. This has its adherents.^{29 138}

Michels,¹³⁹ in a detailed review of the morphogenesis, function and development of the plasma cell in 1931, discussed the early formulation of morphologic concepts, pointed out that amitosis leading to the formation of multinucleated cells is a frequent phenomenon" and enunciated four main hypotheses of plasma cell origin (listing their proponents). These include (1) 'a histogenous origin from connective tissue cells, including tissue lymphocytes, fibroblasts, clasmatocytes, resting wandering cells, adventitial cells, hemohistioblasts etc.' (Piney, Downey, Naegeli, Maximow and others), (2) a hematogenic origin from emigrated lymphocytes", (3) 'mixed origin from emigrated lymphocytes (monocytes) or pre-existent tissue lymphocytes,' and (4) an origin from immature blood cells (myeloblasts, hemoblasts—erythroblasts, granuloblasts) through aberration or abortion." Michels also mentioned Maximow's tissue culture work (1922-1923) which showed that in explants of lymphoid tissue plasma cells develop from local lymphocytes in the course of two days. Jackson, Parker and Bethea²⁹ noted the similarity of multiple myeloma to lymphomas and said 'The type cell (plasma) belongs beyond question to the lymphoid series, and the clinical picture finds analogies throughout its course in the pathologic and symptomatic picture of the lymphomata."

In the recent literature, increasingly greater mention is made of the origin of these cells ('myeloma' or 'plasma') from the reticulum, to the point now where the hypothesis has gained such widespread acceptance as the statement, 'since the disease originates in the reticulum cell'.¹¹⁰ Osgood¹⁴⁰ stated that 'it is commonly thought that plasmocytes develop from lymphocytes, but I have never

found any evidence of this from my studies of multiple myeloma, plasmocytic leukemia or marrow or blood cultures. It seems certain that they are a distinct and separate line of cells." Both Scott and associates,¹³⁴ and Kracke and Garver,¹⁴¹ who shared this conviction, cited Doan¹³⁶ as holding the belief that the myeloma-plasma cell arises from the reticular cells of the bone marrow and general connective tissue, Churg and Gordon¹³⁰ "stress the probable origin of the myeloma cells from the reticulum of the bone marrow" and cited Klemperer¹⁴² and Rohr¹⁴³ (as did Jones¹³⁷) as pointing out that the "plasma cell" of the myeloma is an abnormal hematic cell, the origin of which may be traced to the primitive reticulum cell of the bone marrow. Cappell¹⁴⁴ said, in reporting 2 cases of multiple myeloma "It might be considered that the abnormal myeloma cells are derived originally from the primitive reticulum cells. Some have differentiated through a myeloma cell of the common type or have even been further transformed into the plasma cell type."

Miller¹⁴⁵ injected tuberculo-protein into the peritoneum of rabbits and observed that the precursor of the plasma cell was the reticular cell and its development could be traced through the blast stage to the typical mature Marschalko-type plasma cell, and finally into the degenerative phase with Russell-body formation. Lowenhaupt¹⁴⁶ examined 12 cases at necropsy and found splenomegaly in all but one. The splenic follicles were separated by wide expanses of plasma cells. Because these germinal centers (and those in the lymph nodes) remained intact even when widely separated by plasma cells, she felt that a hypothesis of lymphoid origin was untenable. She felt that she could detect single plasma cells and clusters of plasma cells hanging from the "reticular framework" into the vascular stream and felt that a "histiocytic origin" was suggested.

Recently, too, Parsons,¹⁴⁷ in a study of irradiated and tumor-bearing mice, arrived at much the same conclusion with regard to the plasma cells in these nodes. She observed that plasma cells develop locally in many inflammatory processes but that in these experimental mice it was systemic response, provoked by an agent acting on lymphoid tissue generally and primarily on the reticulum. Reticulosis was an early and constant feature and occurred coincidentally with the disappearance of lymphocytes. She wrote

Examination has given no evidence of the development of plasma cells from lymphocytes, which may indeed be entirely absent from the glands when plasma cells are abundant and active. Mitosis of lymphoid cells is rarely observed, even in the germinal centres where the reticulum cells appear to be in active proliferation and when karyokinesis of these and of plasma cells throughout the glands is marked. Proliferation of reticulum seems to start at the periphery and to spread inwards to the medulla, the existing plasma cells being in direct contact with these areas and having little relation to the diminishing lymphoid tissue.

In the early stages such glands show strands of branching cells forming a close network and staining more deeply with pyronin than normal reticulum. The nucleus is frequently eccentric. Later a perinuclear pallor develops in many cells, the nuclei of which are more darkly staining and have become more eccentric. Around the hilum the intersinusoidal cords contain few coalescing reticulum cells but only free mature and immature plasma cells.

Maximow and Bloom (1928) relate the plasma cell to the hemocytoblast, which they consider identical with the lymphoblast. No evidence has been found that this free mesenchymal cell is the direct

forerunner of the plasma cell, since the cells responsible for the plasmacytosis seen in the glands of the experimental mice appear to be the fixed reticulum cells of the stroma and identical with Maximow's fixed undifferentiated mesenchymal cells.

Hertzog and Schleicher¹⁰⁹ again stated "that the myeloma cells arise from the reticulum. This slide shows myeloma cells arising from vascular adventitial cells considered undifferentiated reticulum cells." Gordon and Schneider¹⁰⁸ noted that Kracke and Garver,¹⁴¹ and Curtze¹²³ had suggested that plasma cells originate from primitive reticulum cells. They then said "The changes found in the hematopoietic organs in this case lend support to the view expressed by Kracke and Garver. At least strong presumptive evidence of this is supplied by the atypical reticulum cell hyperplasia found in the marrow, spleen and lymph nodes, and the transitional forms between reticulum cells and plasmablasts." Closely related to the concept of reticulum cell origin is that concept which holds that either the hemocytoblast^{9, 62, 145} or the hemohistioblast^{13, 116} is the parent cell.

C. DEGREE OF MALIGNANCY

In more than 230 references, only a handful of observers have commented on such aspects of the disease as they believed influenced the prognosis or mentioned factors which might be so implicated. In Morison's¹⁴⁹ fourth case, the disease was of brief duration and was "relatively anaplastic." Kolodny⁷⁴ noted that "among plasmacytomata one encounters a small and large cell variety, the latter are said to be of more rapid growth and somewhat worse prognosis." Caylor and Nickel¹⁵⁰ suggested that the "myelocytic" myeloma is more malignant than the plasma cell type. Gordon and Schneider's¹⁰⁸ case showed a very bizarre, anaplastic and pleomorphic marrow picture. The patient survived only about six weeks from the onset of symptoms. Mallory¹⁵¹ said "I have never seen a bone marrow with so many immature plasma cell elements suggesting something very acute and very malignant." Moss and Ackerman¹³³ remarked about the myelomas with large numbers of circulating myeloma cells "Thus the readiness with which plasma cells tend to enter the blood stream should be a measure of malignancy. Such a statement seems logical, but it has not been proven." Hertzog and Schleicher¹⁰⁹ in presenting 3 cases of plasma cell myeloma at a pathologic conference, stated that "the solitary types are of a high degree of malignancy," and "one can estimate to some extent the clinical degree of malignancy by the amount of secretory activity of these cells."

Nothing definite can be concluded from reviewing these brief remarks but the suggestion is present that pleomorphism, anaplasia and cytologic immaturity are associated with a shorter clinical course.

REVIEW OF CASES

In the normal bone marrow, plasma cells average approximately 1 per cent^{4, 7} of the leukocytic series. In diseases other than multiple myeloma, such as chronic inflammations, granulomas, measles, roseola infantum, carcinoma, aplastic anemia, infectious mononucleosis, Boeck's sarcoid, cirrhosis, lymphogranuloma

inguinale, monocytic leukemia, periarteritis nodosa and so forth, plasma cells may occur in excess numbers in the blood and bone marrow. Ordinarily this does not give rise to confusion with multiple myeloma, particularly if the diagnosis is clinically apparent. However, in an indeterminate situation, in which the bone marrow smear is expected to be of positive diagnostic value, some question may arise whether these excess and often abnormal plasma cells are not a part of a myelomatous process. This can not always be settled unequivocally on one examination, particularly negatively. However, in the great majority of cases little doubt remains.

The type of cell customarily found in smears of sternal marrow in multiple myeloma most resembles, of the normally occurring bone marrow elements, the plasma cell. The characteristics which distinguish the myeloma cell from the normal plasma cell have been described frequently in the past,^{4, 7, 39, 84, 148} and there is little that is new to be added to these descriptions. Nevertheless, setting down here again the observations made in these cases may prove useful in re-emphasizing the specificity of this picture as a pathologic, as well as a clinical, entity.

Sternal marrow aspirations in 51 cases were studied, 1 case twice with a three year interval, and 20 more subsequently reviewed after this study had been completed. These latter 20 cases will not be included except as has otherwise been noted.

The first sternal aspiration on a patient who had multiple myeloma was performed at the Mayo Clinic in 1939. In that year 2 cases were noted, in 1940, 5 cases were observed, in 1941, 3 cases, in 1942, 4 cases, in 1943, 6 cases, in 1944, 8 cases, in 1945, 15 cases, in 1946, 19 cases, and in 1947, at the time of this report, 9 cases. Follow-up reports were sought and obtained only on those patients studied who had been examined at the clinic prior to January 1, 1946.

GENERAL CONSIDERATIONS

The size of the cells found varied approximately from 12 to 60 microns, considering the longest diameter of the cell, multinucleated cells not included. This variation occurred within cases as well as between cases. In some instances a marked uniformity of size and shape was the rule (fig. 1), in some cases moderate variation occurred and in still others, very bizarre appearing cells (fig. 2) were observed, varying greatly in size and shape, with, however, almost indistinguishable gradations between stages.

The cytoplasm was abundant as a rule, even in the very immature cells, usually equaling the size of the nucleus and often exceeding it fourfold to fivefold. It stained deeply basophilic, when the usual Romanowsky stains were used, often staining more deeply at the periphery to form a sort of 'rim' (fig. 3). In color it varied from a deep, slaty, cloudy blue to a rather bright and somewhat clearer blue. The cytoplasm was somewhat granular or pock-marked in appearance and not a clear homogeneous medium as is seen in the lymphocyte. Occasionally a perinuclear light, clear area or Hof was seen but this was inconstant. The character of the cytoplasm was one of the most persistently uniform and striking features of these

cells which held them together as a class, and impressed one with their similarity to the normal plasma cell

The nucleus was often eccentric and, in some cases, almost constantly so. Here again the relationship to the plasma cell was emphasized. However, at this point, nuclear similarity usually ceased. Most nuclei had a finer chromatin pattern than the plasma cell, and this usually contrasted sharply with the parachromatin. A few had well-differentiated nuclei with heavy chromatin blocking (fig 1). Among the rest were fine reticular patterns (fig 4), diffuse stranded chromatin (fig 3), or a granular chromatin background surrounding islands of condensed chromatin "dots" (fig 5). As the cellular differentiation decreased, the tendency to eccentricity seemed to be proportionately reduced, though this still did occur in obviously immature or poorly differentiated cells.

FIG 1 Uniform, mature, differentiated picture in a chronic multiple myeloma. Patient living after eighty-eight months ($\times 720$)

One, and occasionally more, large clear nucleoli were seen in the nuclei of most myeloma-plasma cells. These usually stained a pale sky-blue, lighter than the rest of the cell, although occasionally of a deeper blue. In all but two of the 51 cases studied there were more than 5 per cent of nucleolated myeloma-plasma (per 100 myeloma) cells. In six instances, nucleoli were noted in virtually all of the myeloma-plasma cells, and in about 57 per cent (29 of 51) of cases there were nucleoli in at least half of the myeloma cells present.

As might be expected, if amitosis were as common in myeloma-plasma cells as it is in normal plasma cells,¹³⁹ many multinucleated cells would be seen. This was so. At least one multinucleated cell was noted in each case studied, and the frequency rose to more than 5 per cent of all myeloma cells present. (The number of nuclei per cell was noted to exceed twelve, although two to three were more usual.) This

tendency to "giant cell" formation has led to various diagnostic difficulties, as these hypernucleated cells may give rise to the belief that they are megakaryocytes,

FIG. 2a and b These illustrations were both made from the same smear on the same patient and demonstrate vividly the degree of anaplasia and pleomorphism which may exist in the bone marrow in this disease ($\times 725$)

or (in tissue) tumor giant cells, or Sternberg-Reed cells. Mitoses were not common, but in those cases in which they were seen easily, the outlook was grave.

In all but 2 cases (rarely in 2 others) cytoplasmic extrusions were noted dis-

seminated freely through the marrow field. These extrusion bodies were identical in all respects with the cytoplasm of the myeloma cells. They stained alike, had

FIG 3 Myeloma cells here constituted 2.5 per cent of leukocytic elements, lymphocytes 41 per cent. Note rim at periphery of myeloma cell ($\times 900$)

FIG 4 MYELOMA CELLS WITH A RETICULAR PATTERN IN THE NUCLEI ($\times 720$)

the same internal granularity," contained vacuoles when the myeloma cells did and even contained Russell bodies in one case in which they were numerous. In

several cases they seemed to arise from buds or pseudopodia extending from the myeloma cell. These same extrusions have been seen in the peripheral blood in such

FIG 5 PROMINENT AREAS OF CHROMATIN CONDENSATION SINGLE NUCLEOLUS ($\times 720$)

FIG 6 Russell bodies may be seen in the upper center cell. Smaller ones were present in the other cells but are not apparent here ($\times 850$)

cases. That this has special diagnostic value, however, is doubtful as the same phenomenon may be seen in other conditions, particularly the lymphocytic and mono-

cytic leukemias In this connection, it is of some interest to note that Sabin is quoted by Lowenhaupt¹⁴⁶ as showing that release of globulin by clasmotocytes is associated with the shedding of cell cytoplasm into the blood stream However, despite the attractive possibility that it might, no relationship could be noted between the rate of occurrence of these cytoplasmic bodies and the presence of Bence Jones proteins in the urine, or the degree of elevation of the serum proteins

Among the common degenerative changes, so-called, that occur in plasma cells, vacuolization was noted often in the myeloma-plasma cells In some instances, cells were literally riddled with vacuoles, and in at least two instances the nuclei were involved as well An effort to stain such nuclear vacuoles with amyloid stains met with negative results in a recent case in which this was attempted Appreciable vacuolization was noticed in more than half of the cases (29 of 51) Russell bodies (fig 6) were not as numerous, however, even in those cases in which they were seen, although there were two instances in which this was not so They were observed in 11 cases altogether, a trifle more than a fifth It may be mentioned in passing that as recently as 1937,¹⁴⁸ it was stated that Russell bodies had not been demonstrated in the myeloma cell

As might be expected, rouleaux formation in the sternal marrow aspiration was noted with approximately the same frequency as it was in the peripheral blood, 78 per cent

An attempt was made to correlate the cytologic findings with the presence of Bence Jones proteins in the urine, according to Hertzog and Schleicher's method,¹⁰⁹ or any other that might suggest itself No consistent cytologic property was noted, the occurrence of Russell bodies was without significance, as was the presence of vacuoles, or cytoplasmic extrusions The state of cellular differentiation likewise was immaterial

Schleicher¹⁰⁹ suggested that during the "phase of growth" in which the cells are uniform in size and the cytoplasm stains deep blue no Bence Jones protein will appear in the urine On this basis he correctly predicted that Bence Jones proteins would be absent from the urine in a case described "When the cells secrete globulins they become larger and vary in size The cytoplasm appears to be vacuolated and stains irregularly" Disappointingly, in several of our most monotonously uniform cases Bence Jones proteinuria occurred as it did in the case with the clearest, bluest cytoplasm Conversely in some of the cases with large, pleomorphic cells with deep, irregularly staining and vacuolated cytoplasm, Bence Jones proteinuria was not present Hence it has been impossible at present to duplicate Hertzog and Schleicher's results

CELL TYPE

Myeloma-plasma cells were seen in every case, now totaling 71, without fail and consequently a diagnosis of plasma cell myeloma was made in each instance There were no exceptions However, it should be noted carefully that the myeloma-plasma cell was not the predominant marrow cell in every case In fact, it was not the predominant cell in more than a quarter, or 13, of the cases Lymphocytes were present in equal or greater numbers in 11 of these 13 cases Figure 4 shows the char-

acteristic myeloma-plasma cell which was present in a smear in which 41.5 per cent of the cells were lymphocytes, while only 2.5 per cent were myeloma cells.

FIG 7 FIXED TISSUE SECTION FROM BONE MARROW SAME CASE AS FIG 2

Fig 8 Typical myeloma-plasma cells from a case interpreted as Hodgkin's disease on the basis of examination of fixed tissue ($\times 850$)

Of these, 39 of the 100 myeloma cells enumerated had nucleoli. This patient was a man, aged 50, who had suffered from low back pain associated with progressive

weakness and paralysis of his legs for a year prior to his admission to the clinic. Osteolytic lesions were noted in the roentgenograms of his thorax, thoracic and

lumbar segments of the spinal column, pelvis and femora with compression of the eleventh and twelfth thoracic vertebrae. No test of his urine for Bence Jones pro-

FIG 11 More mature myeloma cell shows definite plasma cell characteristics now. Shrivelled nucleolus still can be made out at the 5 o'clock position ($\times 1,120$)

FIG 12 Cell very suggestive of reticulo-endothelial cell. The nuclear pattern is fine and skeinlike, there is no blocking of chromatin nor any evident tendency to condensation. The cytoplasm is pale. The outline of a large nucleolus may be seen. This and the following four cells were noted in the peripheral blood of the patient whose sternal marrow was illustrated in the preceding three figures ($\times 1,000$)

teins was made. The concentration of protein was 10.2 Gm per 100 cc of serum and albumin-globulin ratio was 1:3.9. The patient died at home four months later.

In 4 of the 11 cases mentioned, the lymphocytes exceeded the myeloma-plasma

cells by less than 5 per cent, which actually means that they occurred with approximately equal frequency in these cases. In the other 2 of the 13 cases, nucleated erythrocytes were present in numbers approximately three times as great as that of any other cell. In these 2 cases, characteristic myeloma-plasma cells were present to the extent of 16.5 per cent and 42.5 per cent of the leukocyte line.

The implications of this in the examination of fixed tissue should be apparent, namely, the possibility of designating the case as one of lymphocytic, erythroblastic, or myelocytic myeloma (here the oxidase reaction would be positive) on the basis of the predominant cell type.

Another of the hazards of tissue diagnosis is exemplified by the following case. A man sixty-five years old presented himself at the clinic with a three week history of back pain which he first noticed after climbing a fence. Rapid progression and deterioration ensued until the patient was disabled by his pain at the time of admission, just three weeks after its onset. He had been "completely well" prior to that time. An intensely tender tumor was noted medially in his right clavicle and roentgenographic examinations of his skull, thorax, and spinal column revealed multiple discrete osteolytic lesions. Bence Jones proteins were noted in his urine. His serum proteins were normal and the concentration of urea was 110 mg per 100 cc of blood. He died at home within the following week.

Examination of sternal marrow smears from this patient showed an extreme degree of pleomorphism (fig. 2). Eighty-five per cent of the myeloma cells present were immature or poorly differentiated and virtually all contained nucleoli. Although the more differentiated cells (15 per cent) in the smear (fig. 2a) clearly established the identity of these cells, sections of tissue secured at the time of sternal aspiration would have been called "myeloblastic" (fig. 7), if, indeed, a diagnosis of multiple myeloma had been sustained at all.

More recently a 48 year old man appeared at the clinic with a four month history of thoracic and back pain, and severe anemia. His liver was enlarged and he had axillary adenopathy. On roentgenography his skull, ribs and spinal column were observed to be involved with multiple punched-out osteolytic lesions. The concentration of hemoglobin was 4.35 Gm per 100 cc of blood, erythrocytes numbered 1,390,000 and leukocytes 3,800 per cubic millimeter. Excessive rouleaux formation and promyelocytes were seen in smears of his peripheral blood.

Albuminuria was graded 2 to 3 (on the basis of 1 to 4, in which 1 designates the mildest and 4 the most severe condition), but the urine was negative for Bence Jones protein on two occasions. The erythrocyte sedimentation rate was 172 mm in an hour (modified Westergren) and the total proteins were 9.2 Gm per 100 cc of serum. He had an albumin-globulin ratio of 1:1.51, and a concentration of urea of 82 mg per 100 cc of blood.

Sternal aspiration revealed a typical plasma cell myeloma of a poorly differentiated type with 30.5 per cent of myeloma-plasma cells with 2.5 per cent multinucleated (fig. 8). However, at necropsy, the examination of the fixed tissues presented a picture which was interpreted by the pathologist as being that of Hodgkin's disease, including a heavy reticulum and Dorothy Reed or Sternberg-Reed cells (that is, multinucleated cells with two or three nuclei).

It may be seen, then, that though the degree of plasma-cellular differentiation may vary strikingly between cases and even within cases, a strong bond of cytologic similarity exists between all cases, and the transition from cell to cell can be observed to proceed through scarcely perceptible gradations. Three important pitfalls to proper diagnosis were recognized (1) immaturity, (2) multinuclear plasmagiant cells, and (3) lack of preponderance of myeloma cells in some cases

HISTOGENESIS

One looks to the more differentiated cells in a tumor to indicate its destination, and to the least differentiated cells to reveal its origin. In the immature myeloma cell, a granular, finely reticular (leptochromatic), skeinlike chromatin is frequently

FIG 13 Here is a cell almost identical with that in figure 12 with two important exceptions (1) the nuclear pattern is becoming heavier, and (2) a tendency toward condensation of the chromatin is suggested. A large nucleolus is readily seen ($\times 1,000$)

encountered. In certain cases (fig 4), seen even in the late phases, it is strikingly apparent. This in itself would seem to be strong support for the hypothesis that the myeloma cell is derived from the reticulum, as has been so often stated by others and noted earlier in this paper.

Further strengthening this conclusion are the findings in the following case which I believe is, in many ways, unique. When first examined in the spring of 1940, the patient, a woman 60 years old, had moderate hepatosplenomegaly, osteolytic lesions in her skull and extremities (the only regions of which roentgenograms were taken), repeatedly positive reactions for Bence Jones proteinuria, albuminuria, grade 4, moderately severe anemia and the peripheral blood picture of

leukemia. A sternal aspiration at that time showed 11.5 per cent of characteristic myeloma-plasma cells (figs 9, 10 and 11), and a diagnosis of multiple myeloma was made. A review of the peripheral blood smear taken at that time shows characteristic myeloma cells present as well as myeloid immaturity (leukemoid reaction). Subsequently, however, the patient's liver was found to "fill her whole abdomen" and the peripheral blood contained many cells almost indistinguishable from (if, in fact, they were not) reticulo-endothelial cells. These final developments were so marked as to cause the clinician to change the final diagnosis to reticulo-endotheliosis.

Repeated careful reviews of all the slides made on this case from the marrow and peripheral blood emphasize that myeloma-plasma cells were present from the start.

FIG. 14. Here the trend becomes more pronounced. Three definite areas of condensation of chromatin are visible in the nucleus. Note also that the cytoplasm is darker and contains vacuoles ($\times 1,000$).

to the finish and that an imperceptible transition existed between the most reticular cell, the completely characteristic myeloma cell (figs 12 to 16) and the well-differentiated (though atypical) plasma cell. Clinically, this case fitted best a diagnosis of multiple myeloma in a 'plasma cell leukemia' phase. Histologically, the suggestion was almost inescapable that this was a multiple myeloma, that multiple myeloma arose from the reticulo-endothelial cell and that here, in a profound instance of such a disturbance, in which the marrow elements were being liberated into the peripheral blood, the almost completely undifferentiated reticulo-endothelial cell itself was finding its way into the circulation along with its more differentiated counterpart, the myeloma-plasma cell. No other explanation so well satisfies the known facts about multiple myeloma, the experimental studies on the origin of the plasma cell and the very unusual findings in the case mentioned.

ESTIMATION OF DEGREE OF MALIGNANCY

With the methods used, it was observed that those cases in which there was a marked degree of pleomorphism, often associated with frequent mitoses and notable immaturity, bore the poorest prognosis. Ten cases fell into this category. None of the patients in this group survived longer than twelve months after the onset of symptoms and the mean was 6.3 months. The patient who survived the longest in this group, twelve months, had the most uniform picture, despite the high percentage of myeloma cells present and the reticular, leptochromatic character of the nucleus (fig. 4) in almost all of the cells. The case of the 65 year old man previously described (fig. 2) most strikingly portrays this group. The total duration of this

FIG. 15 More clumping of chromatin is seen here and the cell no longer resembles a reticulo-endothelial cell ($\times 1,000$)

patient's disease from the onset of symptoms was one month and his marrow was most anaplastic and pleomorphic.

At the other end of the scale were the 7 cases in which uniform, mature-appearing plasma cells comprised almost the entire number of myeloma cells present, 96 per cent or more. Of the 7 patients, 3 died at the end of forty-two, sixty, and seventy-one months, respectively, and 4 were living when last heard from at the end of twenty-four, twenty-six, eighty-eight and sixty-seven months.

Typical, perhaps, of this group of patients is the case of a woman, 40 years of age, who was first seen in 1941, seven months after the onset of pain in the lower part of her back. She had a palpable liver. Roentgenograms revealed multiple punched-out osteolytic areas in her skull with osteoporosis involving her spinal column. Bence Jones proteinuria was present. Serum proteins were not determined. She was moderately anemic, the concentration of hemoglobin being 8.4 Gm per 100

cc of blood and erythrocytes numbering 3,410,000 per cubic millimeter of blood, and she had mild leukocytosis, the leukocytes numbering 11,300 per cubic millimeter of blood. There was albuminuria, grade 3 (on the basis of 1 to 4, in which 1 designates the mildest and 4 the most severe condition) and a concentration of urea of 38 mg per 100 cc of blood.

The patient's only treatment consisted of orally and parenterally administered calcium salts prescribed by her veterinarian brother. Two years later she wrote that she felt better than she had in ten years and was mowing her own lawn. When heard from in 1945, fifty-eight months after the onset of her illness, she was hospitalized for a pathologic fracture of her left hip. She had had no treatment whatsoever in the preceding two years. She was last heard from in April, 1948,

FIG. 16 At this point a moderately well-differentiated myeloma-plasma cell emerges. It will be noted that there has been a gradual loss of cytoplasm, but in each instance the nucleus has tended to remain eccentric ($\times 1,000$).

eighty-eight months after the onset of her illness, and was still feeling fairly well. Ninety-nine per cent of this patient's myeloma-plasma cells were considered to be mature (fig. 1).

Of the remaining patients, 2 could not be traced and 2 were still living. The duration from the onset of symptoms regarded as referable to the disease varied from five to forty-four months. As was anticipated, the trend was toward a longer survival among those patients in whom the greater number of myeloma cells was mature. Of this intermediate group of patients, the following case history is probably most illustrative.

A man, 45 years old, was first seen at the clinic in February, 1945, with a history of anemia and weakness of one and a half years' duration. For the preceding six months he had manifested a marked tendency to bleed from his nose, gums, and

FIG 17 The column at the left represents a differential count of one hundred myeloma cells on each case followed for at least a year. The bars immediately to the right indicate the duration of the disease in the corresponding case from the onset of symptoms.

TABLE 3 —Condition at Last Report. A Summary of the Survivals among those Patients Depicted in Figure 17

Survival from onset, years	Grade 1*		Grade 2		Grade 3	
	Living	Dead	Living	Dead	Living	Dead
0-1			2†	4		9
1-2				11		1
2-3	2		1	5		
3-4		1	1	2		
4-5		1				
5-6	2	1				
Total	4	3	4	22	0	10

* Graded 1 to 3 on the basis of 1 being the least malignant and 3 being the most malignant
† Untraced

lacerations of his skin. Osteolytic lesions were demonstrated in his roentgenograms. Bence Jones proteins were found in his urine and his total serum proteins were 11.8 Gm per 100 cc of serum with an albumin-globulin ratio of 1:2.19. The erythrocyte sedimentation rate (modified Westergren method) was 151 mm at the end of an hour. Stem cells were occasionally seen in smears of the peripheral blood and there was excessive rouleaux formation.

The patient had no treatment other than local radium applications for severe epistaxis and died ten months later. Thirty-six per cent of the myeloma cells were of the moderately immature type, and the other 64 per cent were rather well differentiated.

All of the foregoing cases are summarized in table 3, and the duration of the disease in each case is graphically portrayed in figure 17.

It will be observed that several patients of the last-mentioned intermediate group lived only a very short time after the onset of symptoms. Since it is perfectly obvious that the onset of symptoms and the onset of the pathologic process in this disease do not correspond, it was not surprising to note some lack of correlation, and it was in this area that the value of the method used was most limited. It may also be mentioned, though this too, should be apparent, that the discrepancy between the onset of the disease and the onset of the initial symptom is not a constant. However, as will be noted from figure 17, the differential cytologic picture does bear a rather significant relationship to the expected duration of the disease in the group as a whole.

SUMMARY AND CONCLUSIONS

Generalizing, it can be said that the pathologic cells seen in smears of the bone marrow in multiple myeloma resemble the plasma cell and vary from the very anaplastic and immature cell to the well-differentiated and almost characteristic plasma cell.

The feature which the "myeloma" cell shares with the plasma cell is the abundant, granular, basophilic cytoplasm which tends to be fragile and undergo the same degenerative changes in each, namely, the formation of Russell bodies and vacuolization. Fairly frequently a perinuclear clear area or Hof is present and the nucleus tends to be eccentrically placed. Cytoplasmic extensions or pseudopodia may also be seen in either case, but they occur more often and more dramatically in instances of multiple myeloma. Multinucleated cells are commonly seen.

In addition, myeloma-plasma cells will often have a large clear nucleolus and a leptochromatic nucleus and will exhibit a tendency to the formation of isolated areas of condensed chromatin. Cytoplasmic extrusions, free cytoplasmic bodies, occasionally complete with Russell bodies and vacuoles are almost universally present.

All cases were of the plasma cell type, there was no exception. In these cases, the myeloma-plasma cell constituted from 2.5 to 96 per cent of the leukocytic elements present. The opinion was expressed that all so-called types of multiple myeloma are merely variations in differentiation of this same cell.

It was noted that anaplasia, hypernucleation and lack of plasma cell predomi-

nance in certain cases were diagnostic pitfalls. Additional evidence was adduced to confirm the reticulo-endothelial origin of the myeloma-plasma cell. It was further observed that certain prognostically valuable information could be gleaned from a careful review of the cytologic characteristics in these cases.

UNUSUAL REMISSION AFTER RADIOPHOSPHORUS THERAPY IN A CASE OF "ACUTE PLASMA CELL LEUKEMIA"

By EDWIN D. BAYRD, M.D., AND BYRON E. HALL, M.D.

THE DESIGNATION, "acute plasma cell leukemia," has been used in this case for descriptive purposes and is not intended to convey the impression that we conceive of plasma cell leukemia as an independent process apart from the myelomas. Our experience with this disease and that of others have led us to agree with Patek and Castle¹ that plasma cell leukemia merely represents a phase or extension of multiple myeloma. The reasons for this have been stated in detail previously.² No attempt will be made at this time to review the literature on this subject. Two recent articles^{3, 4} on plasma cell leukemia have brought the literature up to date and any report from us would be incomplete without an analysis of the other cases from the Mayo Clinic which will be attempted in the future. However, it should be mentioned that cases in which the leukemic aspects of the disease predominate are exceedingly unusual (reported in only four instances without roentgenographically evident lesions of bone) and, so far as we know, a remission in such cases has heretofore been unrecorded.

From the Division of Medicine, Mayo Clinic, Rochester, Minnesota

REPORT OF A CASE

A 59-year-old barber of Italian extraction was admitted to the clinic on Jan. 7, 1946. He gave a history of dizziness, thoracic pain and progressive weakness of two months' duration. Three or four weeks before admission a distressing cough and rapid enlargement of cervical and axillary lymph nodes developed.

At the time of admission the patient was too weak to dress himself, was markedly dyspneic at rest, and was racked by coughing.

On physical examination, pallor and moderate to notable enlargement of the cervical, supraclavicular, axillary, epitrochlear, inguinal, and femoral nodes were observed. Basal rales and hepatosplenomegaly were noted. The liver and spleen were firm and extended below the costal margin about 8 cm. By percussion it was determined that the mediastinum was widened. The blood pressure was 122 mm. of mercury systolic, and 68 mm. diastolic. The pulse rate was 96 beats per minute and the temperature was 98° F.

Special smears of the peripheral blood revealed the presence of 41.5 to 48 per cent of plasma cells (fig. 1). Results of the other laboratory examinations of the blood are given in table 1. The bleeding time (Duke's method) was more than a half hour, and the coagulation time was six minutes. Clot retraction did not occur in twenty-four hours. The sedimentation rate of erythrocytes was 120 mm. in an hour (modified Westergren method), the concentration of serum proteins was 9.6 Gm. per 100 cc. and the albumin-globulin ratio was 1:3.74. The value for serum calcium was 8.1 mg. per 100 cc., for serum phosphorus, 3.6 mg. per 100 cc., and for alkaline phosphatase, 2.5 Bodansky units per 100 cc. of serum.

Urinalysis revealed high grade albuminuria, Bence Jones proteinuria, occasional erythrocytes, and granular and hyaline casts.

Roentgenograms of the patient's skull, ribs, spinal column, pelvis, and right femur revealed no osseous abnormalities. The parenchyma of the lung was considered to be infiltrated diffusely, but the condition could not be distinguished roentgenographically from passive congestion. A biopsy of a cervical lymph node revealed, according to the pathologist, lymphoblastoma containing plasma cells and evidence of involvement of the blood vessels. Atypical myeloma with features of lymphosarcoma and leukemia. Results of examination of material obtained by sternal aspiration were considered to be diagnostic of multiple myeloma (fig. 2 and table 2).

The patient was hospitalized upon admission and remained in the hospital during the following forty-eight days. During the first two weeks he received 500 cc of blood and three small doses of radiophosphorus, P^{32} . The latter were given almost out of sheer desperation, without the faintest hope of effecting any perceptible improvement.

FIG. 1 Smear of peripheral blood in January, 1946. Plasma cell leukocytosis and increased rouleau formation are apparent (Wright's stain, $\times 640$).

TABLE 1—Results of Examination of the Peripheral Blood

	Jan 7, 1946	Jan 23, 1946	Sept 23, 1947
Hemoglobin, Gm per 100 cc of blood	10.9	6.8	14.1
Erythrocytes, per cu mm of blood	3,620,000	2,240,000	4,520,000
Leukocytes, per cu mm of blood	25,600	43,400	5,100
Lymphocytes, per cent	17.5	7.0	48.0
Monocytes, per cent	1.5	4.5	6.0
Neutrophils, per cent	37.0	32.5	45.0
Eosinophils, per cent	1.0	0	1.0
Basophils, per cent	0	0	0
Metamyelocytes, per cent	0	2.5	0
Myelocytes, per cent	0.5	3.5	0
Promyelocytes, per cent	1.0	2.5	0
Plasma cells, per cent	41.5	48.0	0
Platelets, per cu mm of blood		55,000	122,000

The patient's condition grew progressively worse until, at the end of the seventeenth day, it appeared to be in its terminal stage. His temperature was 104 F, pulse rate, 108, and respiratory rate, 28. An indwelling catheter was inserted because he could not void; he was incontinent of feces. A bed sore was developing and blood was oozing from his gums. He was drowsy and deaf (this had appeared within

thirty-six hours, two days previously) and a clear yellow exudate was draining from his left ear. Jewel-clear, pemphigus-like vesicles on his neck, arms, thorax, groins and thighs had appeared and subsided

FIG 2 The bone marrow on initial admission shows contrast between the myeloma plasma cells and the lymphocytes. Plasma cells comprise 31.5 per cent of the myeloid elements in this marrow (Wright's stain $\times 640$)

TABLE 2—Results of Examination of Sternal Marrow

	Per cent	
	January 1946	September, 1947
Stem cells	1.0	1.5
Leukoblasts	1.0	2.5
Promyelocytes	1.5	4.0
Myelocytes	9.0	6.0
Metamyelocytes	12.0	14.0
Bands	13.0	21.0
Polymorphonuclear cells	5.0	17.0
Eosinophils	0.5	0.5
Basophils	0	0.5
Monocytes	2.5	3.0
Lymphocytes	23.0	28.5
Plasma cells	0	1.5
Myeloma-plasma cells	31.5	0
Nucleated erythrocytes	35.0	22.5

These were the lesions of clinical pemphigus, but were also deemed to be consistent with the terminal manifestations of a disease such as this

The patient lay quietly in bed, with his eyes closed, occasional twitching of his hands and arms was noted and he responded in only a whisper when spoken to. All reflexes were diminished. His abdomen was distended and his mouth was dry. Noisy bubbling râles obscured auscultation. His spleen was markedly enlarged. Examination of the blood was carried out and results are given in table 1. Penicillin, more blood and more radiophosphorus were given in the ensuing few days.

A little more than three weeks after this seemingly terminal episode the cervical nodes were estimated to be 50 per cent smaller, the lungs seemed clearer, and the spleen was about 25 per cent smaller. The number of plasma cells in the peripheral blood was markedly reduced, and the leukocyte count had dropped to 6,600. However, the erythrocytes numbered only 3,100,000 per cubic millimeter and the value for hemoglobin was only 7.1 Gm per 100 cc.

On Feb. 23, forty-eight days after his admission to the clinic, it was felt that the patient had recovered sufficiently to go home.

FIG. 3. Smear of the peripheral blood in September, 1947. It is apparent that there are no longer leukocytosis, rouleau formation or plasma cells. The lymphocytes and neutrophils are present in approximately equal numbers (Wright's stain, $\times 640$).

In the course of his stay at the clinic, he had received 1,770,000 units of penicillin, 3,000 cc of whole blood and biweekly intravenous injections of radiophosphorus, P^{32} . The total dose of radiophosphorus was 6,135 microcuries.

The patient returned for a recheck on Sept. 22, 1947. The following information was obtained about the interval before his return. He had remained in a hospital elsewhere for three more weeks after his dismissal here and then gradually had become ambulatory. He had received 500 cc of whole blood twice; the second transfusion was in April, 1946. Gradually his strength returned, his thoracic pain subsided, and by Oct. 1946, he had returned to his work on a part-time basis. He had worked daily until the time of his second visit to the clinic and he stated that he was continuing to feel stronger and stronger.

At that time his color was excellent. Lymph nodes, liver and spleen were not palpable. His blood pressure was 130 mm of mercury systolic, and 70 mm diastolic, and results of general physical examination were completely satisfactory.

Also at that time extensive examination of smears of the peripheral blood failed to reveal any plasma cells, merely mild lymphocytosis (fig. 3). Results of some of the laboratory examinations are given in

tables 1 and 2. The value for serum protein was 6.9 Gm. per 100 cc. and the albumin-globulin ratio was 1.9:1. The erythrocyte sedimentation rate was 35 mm. in one hour (modified Westergren method). Urinalysis was carried out twice and results were entirely negative. Roentgenograms of his skull, ribs and right shoulder showed no osseous abnormalities and the roentgenogram of his thorax did not reveal any abnormal condition.

FIG. 4. The bone marrow at the time of the patient's last admission shows an essentially normal spread of cells with active erythropoiesis; 1.5 per cent of normal appearing plasma cells are present (Wright's stain, $\times 640$).

TABLE 3—Results of Various Examinations

	January, 1916	September, 1917
Hemoglobin, Gm. per 100 cc. of blood	6.2*	14.1
Erythrocytes, per cu. mm. of blood	2,050,000*	4,520,000
Leukocytes, per cu. mm. of blood	43,400*	5,100
Plasma cells, per cent	48*	0
Sedimentation rate, millimeters in one hour	120	35
Blood urea, mg. per 100 cc.	54	26
Serum protein, Gm. per 100 cc.	9.6	6.9
Albumin-globulin ratio	1.374	1.91
Serum calcium, mg. per 100 cc.	8.1	9.6
Serum phosphorus, mg. per 100 cc.	3.6	2.9
Albuminuria, grade†	3	0
Bence Jones proteinuria	Present	Absent
Roentgenologic examination of bone	Negative	Negative
Examination of sternal marrow	Diagnostic	Not diagnostic

* These are the most extreme values found in the course of the patient's first visit.

† On a grading basis of 1 to 4 in which 1 represents the least and 4 the most severe condition.

Examination of the sternal marrow (fig 4 and table 2) revealed no evidence of his disease. As a matter of fact, no evidence was found in the course of his whole re-examination. The laboratory findings obtained in the course of his two visits to the clinic are given in table 3 for comparison.

COMMENT

We were at no time prepared for such a startling and unprecedented turn of events. Remission, spontaneous or induced, has not been recorded previously to our knowledge, hence, despite the consistently discouraging results from the use of radiophosphorus in multiple myeloma generally, its use in this case is brought into sharp focus. Its possible value in similar instances is suggested and it is hoped that further experience with radiophosphorus in the treatment of this disease will properly define its usefulness as a therapeutic agent.

BARTONELLA BACILLIFORMIS ANEMIA (OROYA FEVER)

A STUDY OF THIRTY CASES

By WILLIAM E. RICKETTS, M.D.

INTRODUCTION

A SEVERE anemia was noticed in workers stationed in certain localized areas along the deep river valleys in 1870 during the construction of a railroad to Oroya, a Peruvian city located in the Andes. This febrile anemia, called "Oroya fever," was thought to be a new disease. In 1885, Daniel A. Carrión, a Peruvian medical student, developed a fatal anemia with the characteristics of Oroya fever, twenty-one days after self inoculation with blood obtained from a verrucous node of the skin of a patient with *Verruga peruviana*. This proved that the anemia was an initial stage of the latter. Thus the name of Carrión's disease¹ has honored the Peruvian martyr.

Since the etiologic agent of the disease was not known during the last century and part of the first decade of the present, excellent clinical descriptions of the disease² undoubtedly included cases complicated by intercurrent infections. A pleomorphic bacilliform organism was discovered by the Peruvian physician, Alberto Barton, in 1909,³ to be the pathogenic agent of the disease.

The purpose of this paper is to analyze the clinical and hematologic characteristics of a series of 30 cases of anemia with *Bartonella bacilliformis* present in the circulating erythrocytes, an entity herein referred to as *Bartonella bacilliformis* anemia. This study was made in Lima, Peru, from 1938 to 1943.

BARTONELLA BACILLIFORMIS ANEMIA

Bartonella bacilliformis anemia (Oroya fever) is a febrile hemolytic anemia with *Bartonella* parasitizing the erythrocytes. This is an infrequent clinical manifestation of the invasive stage of Carrión's disease. It is interesting to notice that in areas where the disease is endemic and where most of the natives have had the disease, few are thought to have had the anemia. At present, however, there is no statistical report available from these endemic areas indicating the exact incidence of *Bartonella bacilliformis* anemia in Carrión's disease. "Oroya fever," Grave fever of Carrión² are synonyms for this anemia, the most used, Oroya fever, is inappropriate as the *Bartonella* infection does not occur in the Peruvian city of Oroya.

It has distinguishing clinical and hematologic features and develops so rapidly that it can be compared only with the anemia occurring in an acute hemorrhage. This anemia occurs irrespective of age, sex or race. Before the onset of the disease the patients of these series were all healthy, well nourished, young individuals with nothing suggesting a deficient individual resistance.

From the Department of Medicine, San Marcos University, Lima, Peru.

* Now at the Frank Billings Medical Clinic, Department of Medicine, University of Chicago.

The physical findings in the patients with severe anemia are rather dramatic and almost pathognomonic. They are deeply apathetic and have a peculiar discoloration of the skin and sclerae due to the combination of slight icterus with very severe anemia. The conjunctivae and the matrix of the nails are almost colorless and the ears almost transparent. The cardiovascular signs consist of tachycardia, soft hemic murmurs of varied intensity heard over the entire precordium, synchronously there are suprasternal, epigastric, carotid pulsations, the blood pressure is moderately hypotensive and occasionally there is peripheral collapse. Dyspnea is very unusual in anemic cases without intercurrent infections, even with erythrocyte counts below one million, contradicting previous reports,^{2 15} in cases with some intercurrent infection, especially salmonellosis, it is a constant finding.^{13 14} Cough and expectoration with rhonchi and rales on physical examination early in the disease may simulate a primary upper respiratory infection. Cheyne-Stokes respiration has been described.⁵ This occurred only in the complicated cases of the present series. Headache, vertigo, restlessness and drowsiness, tinnitus, insomnia and occasionally angina pectoris are symptoms dependent on the intensity of the anemia. Patients often complain of a feeling of transmitted cardiac beating to the head and ears. 'The patient hears his murmurs,' said Odrizola.²

Thirst and anorexia are common features. The tongue is usually dry with a coffee-brown coating. In the early stages of the anemia, profuse sweating may occur but later the skin becomes very dry, a significant point in the differentiation from malaria. There is a generalized lymphadenopathy with nontender lymph nodes, of 5 to 15 mm, without paradenitis. Enlarged lymph nodes occurred in all except three fatal cases. Enlargement of the spleen which has been described as a constant finding,^{2 5 6} appeared only in the cases with intercurrent infections of this series, thus confirming a previous report.⁷ The liver was moderately enlarged in only 2 of the 15 noncomplicated cases.

Observations on the course and type of fever in the past have been varied and even contradictory.^{8 5 9 2 6 10-13} Often after a variable onset with or without chills, the temperature fluctuates between 37.5 and 38.5 C, but it may be higher or lower, and occasionally patients with severe anemia run an almost afebrile course. The severity of the anemia does not parallel the intensity of the fever. Intermittent fever^{2 9} is usually due to concurrent malaria. Odrizola² observed that in many cases there was later a marked elevation of temperature, which he interpreted as prodromal to a second outbreak or 'hyperthermic' course. This elevation of temperature has been found^{13 14} to be associated with intercurrent infection, usually due to *Salmonellae* organisms.

Petechial hemorrhages in the skin are not uncommon. This is mentioned in the first descriptions of the disease and occurred in the martyr Carrión himself.¹ The pinpoint hemorrhages were originally thought to be produced by the beginning eruption of verrucae² and the epistaxis supposedly produced by verrucae in the mucosa of the nose. This explanation is not satisfactory, for most of the cases with epistaxis occur during the initial stage of the disease when verrucae are not seen. Malo¹⁹ first made this differentiation between the petechiae and the pinpoint verrucae in the skin. The author demonstrated in a previous study that cases with

purpura have a constant thrombocytopenia.¹⁷ Hemorrhage may vary from petechial spots to ecchymoses, epistaxis, gingival hemorrhage, hematemesis or melena.^{17 18 19 20} In Case 1, epistaxis was so intense as to endanger the life of the patient, in Case 4, purpura was probably the cause of death, and in Case 5, which was fatal, large hematomas occurred. Clouding of the sensorium and delirium are rather common.^{21 22} In most anemic cases mental symptoms, such as irritability and insomnia, were of secondary importance. However, in other cases, the mental symptoms were so prominent as to constitute a real psychosis. Piccola²³ first described these psychotic episodes and considered them transitory and related to the course of the disease. Alterations of the memory and consciousness were common. In the present series of 30 cases with bartonella anemia, 8 had meningococcic infection with Case 3, these appeared as the end stage of a very virulent bartonella infection with pronounced anemia. In all other cases, these symptoms were present during the crisis of the anemia, as described in Cases 3, 5 and 6. Pain in the bones, joints and muscles along with cramps may occur, but without the constancy and intensity which are found later in the pre-eruptive stage of the disease.

HEMATOLOGIC FINDINGS

As early as 1898, Tamayo²⁴ and Herccles²⁵ described a fall in the erythrocyte count and in the hemoglobin values together with anisocytosis and poikilocytosis. Since then many hematologic studies have been made,^{26 27 28} including a very complete monograph by Hurtado et al.¹⁵ The hematologic findings in 14 cases in this series with apparently uncomplicated bartonella anemia are included in tables 1A and 1B. Hematologically, this anemia is characterized by a sharp drop in the erythrocyte count, which may be so intense as to reach 0.5 million red cells, as is illustrated by Cases 1, 3, 5 and 7. This drop occurs in the first two to four weeks of illness. In Case 3, the erythrocyte count on the day of death, the tenth day of symptoms, was 0.625 million per cu. mm. The anemia is macrocytic and usually hypochromic. Case 1 had a mean corpuscular volume of 198 cubic microns, with a mean corpuscular hemoglobin concentration of 29.8 per cent. The peripheral blood shows marked regenerative activity of both erythroid and myeloid series. The number of nucleated red cells may be exceedingly high. Case 1 had 20 erythroblasts and 461 normoblasts per 100 leukocytes, or 37,164 normoblasts per cubic millimeter. The hematocrit decreased proportionally to the fall in the erythrocytes and in Case 3 reached 9.81 per cent. The lowest hemoglobin value, 1.77 Gm. per cent (using the Evelyn colorimeter) in this series of cases occurred in Case 2 who recovered. Frequently, the erythrocytes show light refractile basophil granulations, nuclear particles, Howell Jolly bodies, polychromasia, poikilocytosis and anisocytosis. Reticulocytes may increase to 50 per cent. The pathognomonic sign of the disease in the erythrocyte is the bartonella bacilliformis. This organism is very polymorphous. In Giemsa staining, it appears as red-violet rods situated on the red cells. The "bacilliform" bodies may be as numerous as 20 on each erythrocyte in heavy infections (fig. 1). The length of the organism varies from 1 micron to 3 microns by 0.25 micron to 0.50 micron. They are dis-

FIG. 1

Case 3 Massive parasitism of erythrocytes by *Bartonella bacilliformis* in the peripheral blood. Bartonellae are present on the red cells, and outside the cells. Two erythroblasts and two myeloblasts are also seen. $\times 2200$ Giemsa stain.

tributed in rods in a Y, V, or chain appearance. They may be curved and may show polar enlargement.⁴ These organisms are well stained by the May-Grunwald-

Giemsa method or by any of the modifications of the Romanowski method (fig 1). The relation of the bartonellae to the red cells has been a controversial point. Modern studies³⁹ tend to indicate that the bartonellae are not located within the red cells, but are rather superimposed on them.

While leukocytosis has been described in this anemia,^{23, 35-37} others have reported a normal leukocytic count¹⁵ or even a tendency to a leukopenia.^{17, 33} It seems from this study that the leukocyte count varies in each case, and in the same patient during the course of the disease. Slight leukocytosis is not uncommon, but marked leukocytosis in cases without intercurrent infections is extremely rare. This occurred, however, in Case 12 (table 1B) with a leukocyte count of

FIG. 2

Case 1 Parallelism between the symptoms and the temperature and pulse in a case of *Bartonella bacilliformis* anemia. The solid blocks represent a marked severity of the symptoms, the lines indicate a lesser degree of severity (the greater the distance between lines, the less marked are the complaints), the empty blocks represent absence of symptoms.

30,160. A very frequent finding is a shift to the left characterized by the presence of myeloblasts, myelocytes, and metamyelocytes. Eosinophilia existed in only one case where *ascaris lumbricoides* was demonstrated in the stools. The leukocyte count appears to be of value as an index to the course of the bartonella infection and in detecting intercurrent infections.

Cases 1, 2 and 3 which follow illustrate severe bartonella bacilliformis anemia.

Case 1 (Figs. 2, 3 and 4)

A V, a 17 year old Indian laborer, after living for six weeks in an area where Carrion's disease is endemic, developed in the first few days of July, 1938, a general feeling of malaise, fever, profuse sweating, pains in the bones of the hands and feet, shortness of breath on exertion and precordial pain. He was admitted to the hospital in Lima on July 17, 1938, in good general nutrition, appearing anemic and

slightly icteric. There were abnormally intense carotid arterial pulsations synchronous with the pulse, and functional hemic murmurs over all areas of the heart, the blood pressure was 110/50, the pulse 120 per minute, and the respirations were accelerated and very shallow. The patient rapidly became confused, had psychomotor excitability, the anemia increased and the fever continued between 37 and 38.2 C. He complained of occipital headache, precordial oppression and insomnia, epistaxis occurred on several occasions. On July 21, 1938, the erythrocyte count totaled only 0.575 million per cu mm, the hemoglobin was 3.3 grams per cent and the leukocytes 7,600. There was a macrocytosis of 198 cubic microns and 461 normoblasts per 100 leukocytes. The red cells showed marked anisocytosis, poikilocytosis and polichromasia with many bartonella bacilliformis. The Wassermann and Kahn reactions were strongly positive. The symptoms continued unchanged until July 28. On that day, no bartonellae

FIG 3

Case 1 Critical and recovery phases of *Bartonella bacilliformis* anemia, showing the marked increase of the red cells, hemoglobin and hematocrit after the disappearance of the *Bartonella bacilliformis*. At the top, in the bars representing *Bartonella* in red cells, and hemorrhage, solid black indicates heavy concentration of *Bartonella bacilliformis*, gradually widening spaces indicate progressive diminishing number of *Bartonella bacilliformis*.

were present in the erythrocytes. On July 29, the general condition of the patient became worse with insomnia and delirium during the night, he had severe epistaxis with loss of approximately 500 cc of blood, the platelets numbered 80,000, the red cells decreased from 0.82 to 0.62 million. The patient remained apathetic in bed and slight edema of the eyelids was noticeable for the first time. The temperature rose to 39 C. Blood cultures were negative for bacteria other than *Bartonella bacilliformis*. During the first week of August, his general condition improved strikingly despite the fever. The number of red cells increased considerably without any therapy, the symptoms faded and the patient developed a ravenous appetite. On October 11, 1938, before leaving the hospital, the erythrocyte count was 4.84 million/cu mm, the hemoglobin 13.8 grams per cent, the hematocrit 39.1 per cent. The mean corpuscular volume was 81, the leukocytes 5,240. Wassermann and Kahn reactions found strongly positive on admission were considered false. These tests later were repeatedly negative.

This case illustrates a severe bartonella anemia with nearly a half million erythrocytes/cu mm, an unusual intensive erythrocytic regeneration and an exceptional macrocytosis. Nasal bleeding coexisted with thrombocytopenia. Despite a prompt recovery an unexplained febrile episode followed the disappearance of bartonellae from the erythrocytes.

Case 2 (Figs 5 and 6)

V C S, a 21 year old Peruvian male, on April 19, 1941, was sent for ten days to an area where Carrion's disease and malaria are endemic. On July 28, he developed malaria which disappeared after three days of intense antimalaria treatment.

FIG 4

Case 1. Mean corpuscular values during the recovery phase of *Bartonella bacilliformis* anemia showing a striking fall in the mean corpuscular volume.

At the top, in the bar representing *Bartonella* in red cells, solid black indicates heavy concentration of *Bartonella bacilliformis*, gradually widening spaces indicate progressive diminishing number of *Bartonella bacilliformis*.

On November 1, he again developed fever and malaise, preceded by a single chill. Mental stupor, marked psychomotor excitability and delirium soon developed, the fever being slight and continuous. On admission (November 8, 1941), the patient was mentally confused and in such a serious condition that it was thought he would die shortly. There was a very severe anemia and jaundice, functional murmurs were present all over the precordium, the blood pressure was within normal limits, the pulse was 120 and the respirations were regular, 16 per minute. Only a few lymph nodes less than 1 cm in diameter were palpated in both axillae. The urine was normal. The van den Bergh reaction for bilirubin was of an indirect type, and the Wassermann and Kahn reactions were negative. The red count was 0.785 millions/cu mm with 46 per cent reticulocytes, hemoglobin 1.75 grams (Evelyn photocolormeter), hematocrit 11.7 per cent, the mean corpuscular volume was 149.9 cubic microns, and icteric index 15. The white blood count was 13,060, with 58 polymorphonuclear neutrophils (2 myelocytes, 5 metamyelocytes, 15 filamented and 36 segmented cells) and 42 lymphocytes. There were 47 normoblasts per 100 leukocytes. Pronounced anisocytosis, poikilocytosis and polichromasia were found. A very small

percentage of erythrocytes contained coccoid bartonellae After a few days, the existing bartonellae disappeared, the number of erythrocytes increased rapidly, the mean corpuscular values became normal, the slight jaundice cleared, the mental symptoms improved and the fever disappeared In the last two weeks of December and the first week of January, he had transitory pains in the epiphysis of the long bones, in the short bones of the hands and feet and in the kness He had paresthesias, the sensation of small worms in the skin Two red spots not larger than a pinpoint were noticed on the skin, corresponding probably to verrugae in formation No anemia was recorded the day the patient left the hospital, January 22, 1942

This case illustrates a very prompt recovery after a severe bartonella bacilliformis anemia

FIG 5

Case 2. Recovery phase of Bartonella bacilliformis anemia

Case 3

R. H., a 7 year old native Peruvian boy, came from a town where Carrion's disease is endemic. On May 28, 1941, he developed malaise and lack of appetite, however, he continued going to school until June 1. His mother noticed that he had fever, had vomited several times and had become anemic and slightly jaundiced. Two days before admission he became restless and delirious. In view of the seriousness of this condition, he was brought to the Children's Hospital in Lima on June 8, 1941. Physical examination showed a very intense anemia. The sclerae of the eyes were slightly icteric, the pupils were dilated, but reacted well to light. He had meningeal signs, rigidity of the neck, maxillary trismus, loss of tendinous reflexes, and bilaterally absent Babinski reflexes. The lymph nodes in the neck were slightly enlarged, the liver was palpated 3.5 cm below the costal margin in the right mid-clavicular line, there were marked carotid pulsations in the neck, together with functional murmurs all over the precordium. The urine was normal. On July 8, 1941, the erythrocyte count was 0.625 million, the leukocytes 35,000,

reticulocytes 20.2 per cent, hemoglobin 2.4 grams per cent (Evelyn photocolormeter), hematocrit 9.81, icterus index 20, mean corpuscular volume 158.55 cubic microns, mean corpuscular hemoglobin 38.40 micromicrograms, mean corpuscular hemoglobin conc. 24.22 per cent. The differential count was polymorphonuclear neutrophils 44 (5 myelocytes, 5 metamyelocytes, 25 filamented forms and 11 segmented cells), lymphocytes 54 per cent, promyelocytes 2. There were 1 erythroblast and 64 normoblasts per cent. There were pronounced anisocytosis, poikilocytosis and polichromasia. Ninety-six per cent of erythrocytes contained bartonella bacilliformis and as many as 19 bartonellae were present in each red cell (fig. 1). The patient died on July 8, 1941, and no autopsy could be obtained.

FIG. 6

Case 2. Mean corpuscular values in recovery phase of *Bartonella bacilliformis* anemia, demonstrating the remarkable change from macrocytosis to normal values.

A massive fatal invasion of *Bartonella bacilliformis* is observed in this child who died on the tenth day of the disease with an anemia with nearly one-half million red cells almost all parasitized by bartonellae.

Thrombocytopenia occurred in eight cases with purpura and external hemorrhages.¹³ These hemorrhages were transitory and lasted no more than two weeks, being parallel to the drop of the platelet count. Fatal Cases 4 and 5 which follow illustrate thrombocytopenic purpura occurring in *Bartonella bacilliformis* anemia.

Case 4

A S., an 18 year old farm helper, referred his disease to a traumatic accident on the dorsal surface of the right foot, which bled constantly. A local physician diagnosed gangrene of the foot. Careful interrogation, however, disclosed that this patient had been living for three months in an area where Carrion's disease is endemic and three days before receiving the foot wound, he had experienced general malaise and fever. He continued to work despite this symptomatology plus polydipsia and anorexia. After the accident, he noticed purpuric spots in the skin, epistaxis, bleeding of the gums, and a bloody discharge through the wound of the foot. On March 16, physical examination disclosed a well developed and well nourished, slightly jaundiced male, with many purpuric spots in the skin, bleeding of the gums, marked anemia, and petechial hemorrhage in the conjunctiva. Lymph nodes, of 5 to 15 mm, were palpable in the inguino-crural, axillary, epitrochlear and cervical regions. The blood pressure was normal, the pulse 130 and the respirations 42 per minute. Over the first interosseal space on the right foot, there was a contusive wound 2 cm long and 1 cm deep with irregular borders, surrounded by an ecchymotic area of about 4 cm in diameter without signs of inflammation. Many other nontraumatic ecchymotic areas were spread over the body, especially on the anterior wall of the thorax. Coagulation time was thirteen minutes and bleeding time twenty-four minutes. Cultures for other bacteria besides *Bartonella bacilliformis* were negative. The peripheral blood had 0.97 red blood cells, 3,500 white blood cells and the differential was 56 neutrophils, 2 monocytes and 42 lymphocytes. There were 2 orthochromatic normoblasts and 1 plasma cell per 100 white blood cells. There was marked anisocytosis, poikilocytosis and anisochromia (table 1A). There were 50,000 platelets. No bartonellae were found in the red cells, nevertheless, Carrion's disease was diagnosed. The patient was given coagulants, fluids and anti-tetanic sera. He died on the second day of his admission. The gross pathologic diagnoses were terminal pulmonary edema, multiple petechial and ecchymotic hemorrhages, ecchymotic wound of the right foot and Carrion's disease. The stained smears of the spleen had many *Bartonella bacilliformis*.

This case illustrates a fatal thrombocytopenic purpura during a severe *Bartonella bacilliformis* anemia.

Case 5

M. H., a 17 year old farm worker, after spending a month in a locality where Carrion's disease is endemic, on April 15, 1939, noticed fever, malaise and profuse sweating, symptoms which continued on the following days. The patient became anemic, slightly jaundiced and was brought into the hospital in a very critical condition on April 10, with convulsions, marked mental confusion, followed by a loss of consciousness. He appeared to be a well-nourished, well developed, seriously ill boy with a very marked anemia. There were many tiny petechial hemorrhages in the conjunctiva, pulsation of the arteries of the neck, functional murmurs over the precordium, and a slight yellow discoloration of the skin and sclerae. The pulse was 104 per minute, the blood pressure 120 over 70, the respirations were shallow, regular and 23 per minute. Examination of the spinal fluid on admission showed albumin 0.09 Gm per cent, glucose 0.44 per cent, urea 0.25 per cent, chlorides 0.4 mg per cent and 1 lymphocyte per cu mm. The Pandy reaction was negative. Typhoid and paratyphoid agglutinations were negative. The red blood count was 0.765 millions/cu mm (table 1A).

The patient continued with insomnia, a very annoying pulsating feeling in the head and ears, cramps in the epigastrium and right upper quadrant of the abdomen. The anemia increased and the general condition of the patient failed. The slight subicteric color of the sclera and skin disappeared and the icteric index became normal. No bartonellae were found in the red blood cells. The lymph nodes of the neck, inguinal and epitrochlear regions became enlarged. The fever oscillated between 36 and 40°C. On April 18, vomiting and headaches appeared with cough, rhonchi and crepitation of the lungs and on the April 22 many pinpoint purpuric spots were seen in the skin and conjunctiva. The patient became dyspneic and died on May 23. Autopsy showed the following prominent features: hydropericardium of nearly 1.5 liters, extensive petechial hemorrhages in many organs, such as the lungs, liver and spleen, external and internal hydrocephalus. *Ascaris lumbricoides* were found in the intestine.

This case illustrates a fatal recurrence of anemia due to thrombocytopenic purpura while the bartonellae were disappearing from the erythrocytes.

"CRITICAL STAGE"

The term "critical stage" of bartonella bacilliformis anemia has been applied to the period of transition in which the organism suddenly disappears from the red cells.²⁹⁻³⁶ The mechanism of this change is controversial, but it is a fact that within a few days the bartonellae may disappear from the peripheral erythrocytes. The hematologic signs of this transition are as follows: (1) A change in the form of the bartonellae from a bacilliform to a coccoid form (originally described by Barton³ in a report published from Lima in 1908) occurs with the appearance of sphere, hour glass, pear shape and granule forms. These are the coccoid bartonella. (2) Decrease in the number of the parasitized erythrocytes and in the number of bartonellae on each erythrocyte. (3) An increase in the erythrocyte count. (4) A reduction in the indirect hyperbilirubinemia to normal. (5) An increase in the number of reticulocytes. (6) A decrease in the macrocytosis, later in the disease the erythrocytes regain normal size and even have a tendency to microcytosis. (7) A lymphocytosis, the monocytes and eosinophiles reappearing. (8) A shift of the polymorphonuclear series to the "right," a characteristic which persists during the rest of the disease.

Clinically, corresponding with this transition, the fever disappears, the subicteric tinge of the skin and sclera disappear leaving an intense earthen gray pallor. With the prompt rise in the number of erythrocytes the symptoms of anemia, such as fainting, dizziness, tinnitus, etc., disappear, as well as the hemic heart murmurs, the blood pressure rises. The patient appears to be convalescent. However, this sequence of events does not always occur, for clinical improvement may not parallel the disappearance of the bartonellae from the erythrocytes. There may be an increased severity of the clinical course of the disease, which is due to intercurrent infections, or to an atypical course of the disease itself. Occasionally, there is clinically an increased severity of the disease, coexisting with the favorable hematologic findings of the critical stage, despite the fact that there is no evidence of intercurrent infections. In these cases, one finds fever, vomiting, tachycardia, insomnia, delirium and psychomotor irritability. This occurred in Case 6, which terminated fatally.

Case 6

J. M., an 18 year old female cook, lived for four months before becoming ill in an area where Carrion's disease is endemic. On October 6, 1939, she developed a headache followed by a chill, fever, malaise and profuse sweating. Despite the persistence of these symptoms, the patient did not stay in bed, the chills did not recur but the fever was continuous. She developed anemia and a slight yellow discoloration of the skin. On admission to the hospital on October 18, 1939, she appeared well nourished and well developed but was markedly confused mentally. She had severe anemia, slight jaundice, pronounced pulsations of the arteries of the neck and epigastrium, very dry skin, hemic murmurs over the precordium. The blood pressure was 115 over 70. The pulse was 120 per minute, the respirations were regular and superficial, 20 per minute. On October 20, the red count was 1.8 millions, hemoglobin 7.8 grams per cent, the leukocytes 6,080 (table 1A). The red blood cells showed a few bacilliform and coccoid bartonellae. No lymph nodes were palpable. The patient's condition rapidly failed, there was continuous vomiting and diarrhea, rigidity of the muscles of the neck, insomnia, motor excitability and headaches. She developed a deep coma progressively, nystagmus with marked increase in muscular tonicity of the neck and extremities. She had negative tendon reflexes and no Babinski response. A Cheyne-Stokes respiration

developed. The blood cultures were negative on several occasions for bacteria other than *Bartonella bacilliformis*. The detailed information of findings at the autopsy have been reported extensively elsewhere.⁵ No definite complications could be found.

An unusual fatal, short failing, hyperthermic course of the disease is illustrated in this case without apparent intercurrent infection. At the time the *Bartonellae* were disappearing from the erythrocytes, the patient developed symptoms frequently found in cases with intercurrent salmonella infection.

It is not known whether the *Bartonella* infection itself is responsible for death in these cases. The interaction between the *Bartonellae* and the reticulo-endothelial system has been studied extensively.⁴⁰⁻⁴⁵ The *Bartonellae* are found in large num-

FIG 7

Leukocytosis occurring before death in case with *Bartonella bacilliformis* anemia complicated by amebic colitis.

bers in the phagocytic cells, such as the Kupffer cells of the liver, littoral cells of the spleen and of the lymph nodes, indicating clearly that the activity of the *Bartonellae* is centered in the reticulo-endothelial system (figs 8-12).

Intercurrent infections may develop in these patients during the critical period of the anemia when there appears to be a lowered resistance of the host to invading organisms harbored in the gastrointestinal tract. These organisms frequently produce a fatal septicemia. In these cases the symptoms are bizarre and confusing. There is usually a rise in the temperature, tachycardia, diarrhea, dysentery, psychomotor excitability, followed shortly by death. There is a sharp leukocytosis with shift to the left in the polymorphonuclear series and a fall in the number of reticulocytes and normoblasts. This is well illustrated in figure 7, complicated by amebic colitis. Blood cultures are very helpful in determining the complicating organism. In this series of 30 cases, intercurrent infections were detected in 15, of whom 3 developed malaria which was promptly controlled by quinine therapy,

FIG 8

Large splenic blood sinus containing many nucleated red blood cells. The large dark littoral cells contain *Bartonella bacilliformis*. Giemsa stain $\times 580$.

2 out of 3 died with typhoid fever, 2 died of a *Salmonella schottmulleri* infection, 3 died with amebic colitis, and in 3 cases the necropsy examination suggested an anaerobic septicemia due to an undetermined organism.

PATHOGENESIS

Bartonella bacilliformis anemia is a hemolytic anemia in which the destruction of erythrocytes is dependent on the presence of *bartonella bacilliformis* on the

FIG 12.

Section of the liver showing large Kupffer cells, which contain erythrocytes, nucleated red blood cells, and small aggregates of *Bartonella bacilliformis* Giemsa stain $\times 570$

erythrocytes The rate of destruction of the erythrocytes and the increased bilirubinemia¹⁵ are directly proportional to the number of parasitized erythrocytes¹⁵ The anemia is macrocytic in type with signs of increased blood formation young

granulocytes, polychromatophilia, reticulocytosis and nucleated red cells. Hypochromia is a frequent finding but did not occur in several cases of this series (table 1). There is increased urobilinogen excretion in the feces. Hurtado et al.¹⁵ have shown that the fragility of the erythrocytes is normal in this disease. There are no spherocytes and enlargement of the spleen clinically does not occur in the cases without intercurrent infections.^{7, 13} Hemoglobinuria does not occur. An early suggestion was that the bartonella bacilliformis anemia was "Addisonian" anemia. Guzman-Barron⁴⁶ demonstrated the presence of Castle's principle in the gastric secretion, and careful hematologic studies¹⁶ have shown that the anemia is normoblastic and not megaloblastic and is accompanied by marked reticulocytosis. Histologically there is evidence of erythrocyte destruction in the reticulo-endothelial system as the Kupffer cells, littoral cells of the spleen and lymph nodes and other phagocytes appear filled with bartonellae and erythrocytes (figs 8-12).

PROGNOSIS

Bartonella bacilliformis anemia has a severe prognosis, due mostly to the frequency of intercurrent infection produced by varied organisms from the gastrointestinal tract. The host's defenses, already lowered by the bartonellosis, are overwhelmed by the subsequent infection.

In 30 cases studied in this series, 22 died, a mortality of 73 per cent. Fifteen of these cases had intercurrent infection, and of these, 11 died with septicemia of gastrointestinal origin. In a group of 15 cases without evidence of any concurrent infection, 9 died. In only 2 cases (Cases 3 and 5) could the death be explained by the virulence of the infection and the intensity of the anemia. Case 5 apparently died of a thrombocytopenic purpura with 440,000 erythrocytes. In the remaining 7 fatal cases the intensity of the anemia was not severe enough to explain the fatal course, the severity of the disease apparently being due to the bartonella infection itself.

TREATMENT

At present, there is no specific therapeutic agent which acts against the bartonella bacilliformis and the treatment used is largely symptomatic. A great deal of therapeutic effort has been directed toward stimulating the bone marrow. This is of dubious importance in cases without any complication, as the main problem in bartonella bacilliformis anemia is not the formation of red cells but the destruction of erythrocytes. The reticulocytosis is sufficient evidence of regeneration. Case 1 in this series without specific treatment or marrow stimulation showed an extraordinary degree of erythrocytic regeneration, this is seen in every case without intercurrent infection. The sudden transition occurring naturally in the course of the disease with disappearance of the bartonellae from the red cells may give the fallacious impression that a given drug or a treatment is responsible for such change. There is some evidence that liver extracts¹⁶ may accelerate the erythrocyte regeneration.

Blood transfusions appear to be indicated, however, up to the present this method of treatment has been used only occasionally. This is largely due to the

prevailing theory³⁵ that the crisis of the anemia with the disappearance of the bartonella bacilliformis from the red cells is due to the immunity of the red cells toward the bartonellae. Blood transfusion, according to this theory, will alter the immunity since the donor cells are supposedly more susceptible and so more apt to be parasitized. This is not acceptable, as the erythrocytes have never been known to have immunologic activity. The immunologic changes which occur in the host in the critical stage produce the changes both in the shape and in the clearance of the bartonellae from the erythrocytes. This is supported by the fact that the anemia does not recur in the course of the disease, even if fatal intercurrent infection occurs.¹⁴ Small blood transfusions of 300 to 400 cc. used in a very few cases with severe anemia and thrombocytopenia in my experience have proved to be a life-saving procedure. Unfortunately, larger amounts of blood were not available to test any of the patients included in this series. The other main objective in the treatment of bartonella bacilliformis anemia should be the prevention of intercurrent infection. Penicillin has lately been reported in a small number of cases to produce good results in the treatment of the disease.⁴⁷⁻⁵⁰ Further studies are necessary to evaluate the action of this drug. In the future, studies should be directed toward the control of the bartonella bacilliformis, as well as the prevention of intercurrent infection.

DISCUSSION

A severe hemolytic anemia may occur during the invasive stage of Carrion's disease. The pathogenic organism, bartonella bacilliformis, is found in the erythrocytes and on the cells of the reticulo-endothelial system. It has been previously stated that bartonella bacilliformis anemia occurs at any stage of Carrion's disease.^{2, 31 et al} However, there are no proven cases in which this anemia has occurred except in the invasive stage of the disease. Anemias which occur later in the pre-eruptive and eruptive stages, were found in a previous study¹³ to have a different etiology and different morphologic and clinical characteristics. The anemias without bartonellas in the erythrocytes are due to intercurrent infections, hemorrhages, thrombocytopenic purpura or other causes. Recurrences of bartonella anemia did not occur in these series of patients even in cases with fatal intercurrent infections. This is another important fact against the concept³⁶ that blood transfusions should not be given to these patients because of the danger of reinvasion of the erythrocyte by bartonellae. On the contrary it seems from this study that these patients will be greatly benefited by repeated blood transfusions from 600 to 1000 cc. as a supportive therapy against the bartonella infection and the anemia. With the disappearance of bartonellae from the erythrocytes, which occurs during the natural course of the bartonella infection, the red cell hemolysis ceases and there is a spontaneous prompt recovery.

The transition period in which the bartonellae suddenly disappear from the erythrocytes in the circulating blood is characterized by a very low resistance of the host to secondary infection. This accounts for a considerable proportion of mortality in this disease, as is illustrated by 11 deaths occurring in 12 septicemic cases. In only 2 cases (Cases 3 and 5) in which the erythrocyte counts were ap-

proximately 5 million/cu mm could death be attributed to the severity of the anemia. In all the other cases the severity of the disease was due to the bartonella infection or to intercurrent infection and could not be related to the intensity of the anemia.

SUMMARY

Bartonella bacilliformis anemia (Oroya fever) is a febrile hemolytic anemia with distinguishing clinical and hematologic characteristics. It occurs as an infrequent clinical form during the invasive stage. The onset is variable with or without chills, followed by a moderate temperature which does not parallel the intensity of the anemia. Hemorrhages, petechial spots, epistaxis may occur and are due to thrombocytopenia. Clouding of the sensorium and delirium are rather uncommon. There is a generalized lymphadenopathy but no splenomegaly.

The anemia is macrocytic and frequently hypochromic with signs of intense blood formation: young granulocytes, polychromatophilia, reticulocytosis and nucleated red cells. The reticulocytosis may increase to 50 per cent. The pathognomonic sign of the disease is the presence of *bartonella bacilliformis* on the erythrocytes. The leukocyte count varies, slight leukocytosis is not uncommon but marked leukocytosis is extremely rare in cases without intercurrent infections. There is a shift of the polymorphonuclear series to the left, characterized by the presence of myeloblasts, myelocytes and metamyelocytes. The anemia is normoblastic and not megaloblastic. It is hemolytic and the destruction of erythrocytes is dependent on the presence of *bartonella bacilliformis* on the erythrocytes. There is no spherocytosis and the fragility of the erythrocytes is normal. Histologically there is evidence of erythrocyte phagocytosis in the cells of the reticulo-endothelial system, the Kupffer cells, the littoral cells of the spleen and the lymph nodes.

The disappearance of the bartonellae from the erythrocytes occurs in a very few days and is called "critical stage" of the anemia. The hematologic changes of this transition are as follows: a change in the shape of the bartonellae from the 'bacilliform' to 'coccoid' form before complete clearance will take place, an increase in the erythrocyte count, reduction in the indirect hyperbilirubinemia to normal, increase in the number of reticulocytes, reversion to normocytosis, lymphocytosis, reappearance of monocytes and eosinophiles, a 'shift to the right' of the polymorphonuclear series. Corresponding with the clearance of *bartonella* from the erythrocytes, the symptoms dependent on the anemia as well as the fever disappear. Clinical improvement, however, may not parallel the clearance of bartonellae because of intercurrent infections or an atypical course of the bartonellosis itself.

Bartonella bacilliformis anemia has a very severe prognosis, due largely to the occurrence of intercurrent infection by enteric organisms. The treatment today is largely symptomatic as there is no specific agent against the bartonellae bacilliformis infection.

It is suggested that the prognosis may be improved by the use of adequate blood transfusions and the prophylactic use of antibiotics to control intercurrent in

fection At present there is no specific agent against bartonella bacilliformis anemia

CONCLUSIONS

1 Bartonella bacilliformis anemia (Oroya fever) is a type of hemolytic anemia in which the pathogenic organism of the disease is found in the circulating erythrocytes and in the cells of the reticulo-endothelial system

2 Bartonella bacilliformis anemia is macrocytic, frequently hypochromic and occurs only during the invasive stage of Carrion's disease and does not recur in the course of the disease Other anemias which develop later have different clinical and hematologic characteristics

3 The transition period in which the bartonellae suddenly disappear from the erythrocytes depends on immunologic changes of the host toward the bartonella infection

4 The prognosis of bartonella anemia is very grave, as is indicated by a mortality rate of 73 per cent in this series of 30 cases This very severe prognosis is largely due to intercurrent infection which occurred in 50 per cent of the cases studied The most severe prognosis was found in cases with septicemias from enteric organisms, as indicated by 11 deaths out of 12 cases

ACKNOWLEDGMENT

I wish to acknowledge my indebtedness to the attending physicians of Dos de Mayo, Arzobispo Loaiza, San Bartolome and the Maternity and Children's Hospitals in Lima, Peru, for permission to study the above patients I am also very grateful to Dr. Alberto Hurtado for facilities to do the hematologic studies in his Laboratory of Clinical Research, Arzobispo Loaiza, in Lima, and also to Doctors Charles Spurr, Eleanor Humphreys and Matthew Block for advice and criticism in the preparation of this manuscript

slightly icteric. There were abnormally intense carotid arterial pulsations synchronous with the pulse, and functional hemic murmurs over all areas of the heart, the blood pressure was 110/50, the pulse 120 per minute, and the respirations were accelerated and very shallow. The patient rapidly became confused, had psychomotor excitability, the anemia increased and the fever continued between 37 and 38.2 C. He complained of occipital headache, precordial oppression and insomnia, epistaxis occurred on several occasions. On July 21, 1938, the erythrocyte count totaled only 0.575 million per cu mm, the hemoglobin was 3.3 grams per cent and the leukocytes 7,600. There was a macrocytosis of 198.1 cubic microns and 46.1 normoblasts per 100 leukocytes. The red cells showed marked anisocytosis, poikilocytosis and polichromasia with many bartonella bacilliformis. The Wassermann and Kahn reactions were strongly positive. The symptoms continued unchanged until July 28. On that day, no bartonellae

FIG 3

Case 1. Critical and recovery phases of Bartonella bacilliformis anemia, showing the marked increase of the red cells, hemoglobin and hematocrit after the disappearance of the Bartonella bacilliformis.

At the top, in the bars representing Bartonella in red cells, and hemorrhage, solid black indicates heavy concentration of Bartonella bacilliformis, gradually widening spaces indicate progressive diminishing number of Bartonella bacilliformis.

were present in the erythrocytes. On July 29, the general condition of the patient became worse with insomnia and delirium during the night, he had severe epistaxis with loss of approximately 500 cc of blood, the platelets numbered 80,000, the red cells decreased from 0.82 to 0.62 million. The patient remained apathetic in bed and slight edema of the eyelids was noticeable for the first time. The temperature rose to 39 C. Blood cultures were negative for bacteria other than bartonella bacilliformis. During the first week of August, his general condition improved strikingly despite the fever. The number of red cells increased considerably without any therapy, the symptoms faded and the patient developed a ravenous appetite. On October 11, 1938, before leaving the hospital, the erythrocyte count was 4.84 million/cu mm, the hemoglobin 13.8 grams per cent, the hematocrit 39.1 per cent. The mean corpuscular volume was 81, the leukocytes 5,240. Wassermann and Kahn reactions found strongly positive on admission were considered false. These tests later were repeatedly negative.

WILLIAM E. RICKITTS

This case illustrates a severe bartonella anemia with nearly a half million erythrocytes/cu mm, an unusual intensive erythrocytic regeneration and an exceptional macrocytosis. Nasal bleeding coexisted with thrombocytopenia. Despite a prompt recovery an unexplained febrile episode followed the disappearance of bartonellae from the erythrocytes.

Case 2 (Figs 5 and 6)

V. C. S., a 21 year old Peruvian male, on April 19, 1941, was sent for ten days to an area where Carrion's disease and malaria are endemic. On July 28, he developed malaria which disappeared after three days of intense antimalarial treatment.

FIG. 4

Case 1: Mean corpuscular values during the recovery phase of *Bartonella bacilliformis* anemia showing striking fall in the mean corpuscular volume.

At the top, in the bar representing *Bartonella* in red cells, solid black indicates heavy concentration of *Bartonella bacilliformis*, gradually widening spaces indicate progressive diminishing number of *Bartonella bacilliformis*.

On November 1, he again developed fever and malaise, preceded by a single chill. Mental stupor, marked psychomotor excitability and delirium soon developed, the fever being slight and continuous. On admission (November 8, 1941), the patient was mentally confused and in such a serious condition that it was thought he would die shortly. There was a very severe anemia and jaundice, functional murmurs were present all over the precordium, the blood pressure was within normal limits, the pulse was 120 and the respirations were regular, 16 per minute. Only a few lymph nodes less than 1 cm in diameter were palpated in both axillae. The urine was normal. The van den Bergh reaction for bilirubin was of an indirect type, and the Wassermann and Kahn reactions were negative. The red count was 0.785 millions/cu mm with 46 per cent reticulocytes, hemoglobin 17.5 grams (Evelyn photocolormeter), hematocrit 11.7 per cent, the mean corpuscular volume was 149.9 cubic microns, and icteric index 15. The white blood count was 13,060, with 58 polymorphonuclear neutrophils (2 myelocytes, 5 metamyelocytes, 15 filamented and 36 segmented cells) and 42 lymphocytes. There were 47 normoblasts per 100 leukocytes. Pronounced anisocytosis, poikilocytosis and polichromasia were found. A very small

percentage of erythrocytes contained coccoid bartonellae. After a few days, the existing bartonellae disappeared, the number of erythrocytes increased rapidly, the mean corpuscular values became normal, the slight jaundice cleared, the mental symptoms improved and the fever disappeared. In the last two weeks of December and the first week of January, he had transitory pains in the epiphysis of the long bones, in the short bones of the hands and feet and in the kness. He had paresthesias, the sensation of small worms in the skin. Two red spots not larger than a pinpoint were noticed on the skin, corresponding probably to verrugae in formation. No anemia was recorded the day the patient left the hospital, January 22, 1942.

This case illustrates a very prompt recovery after a severe bartonella bacilliformis anemia.

FIG 5

Case 2. Recovery phase of Bartonella bacilliformis anemia

Case 3

R. H., a 7 year old native Peruvian boy, came from a town where Carrion's disease is endemic. On May 28, 1941, he developed malaise and lack of appetite, however, he continued going to school until June 1. His mother noticed that he had fever, had vomited several times and had become anemic and slightly jaundiced. Two days before admission he became restless and delirious. In view of the seriousness of this condition, he was brought to the Children's Hospital in Lima on June 8, 1941. Physical examination showed a very intense anemia. The sclerae of the eyes were slightly icteric, the pupils were dilated, but reacted well to light. He had meningeal signs, rigidity of the neck, maxillary trismus, loss of tendinous reflexes, and bilaterally absent Babinski reflexes. The lymph nodes in the neck were slightly enlarged, the liver was palpated 3.5 cm below the costal margin in the right mid-clavicular line, there were marked carotid pulsations in the neck, together with functional murmurs all over the precordium. The urine was normal. On July 8, 1941, the erythrocyte count was 0.625 million, the leukocytes 35,000,

reticulocytes 20.2 per cent, hemoglobin 2.4 grams per cent (Evelyn photocolormeter), hematocrit 9.81, icterus index 20, mean corpuscular volume 158.55 cubic microns, mean corpuscular hemoglobin 38.40 micromicrograms, mean corpuscular hemoglobin conc. 24.22 per cent. The differential count was polymorphonuclear neutrophils 44 (5 myelocytes, 5 metamyelocytes, 25 filamented forms and 11 segmented cells), lymphocytes 54 per cent, promyelocytes 2. There were 1 erythroblast and 64 normoblasts per cent. There were pronounced anisocytosis, poikilocytosis and polichromasia. Ninety-six per cent of erythrocytes contained bartonella bacilliformis and as many as 19 bartonellae were present in each red cell (fig. 1). The patient died on July 8, 1941, and no autopsy could be obtained.

FIG. 6

Case 2. Mean corpuscular values in recovery phase of *Bartonella bacilliformis* anemia, demonstrating the remarkable change from macrocytosis to normal values.

A massive fatal invasion of *Bartonella bacilliformis* is observed in this child who died on the tenth day of the disease with an anemia with nearly one-half million red cells almost all parasitized by bartonellae.

Thrombocytopenia occurred in eight cases with purpura and external hemorrhages.¹³ These hemorrhages were transitory and lasted no more than two weeks, being parallel to the drop of the platelet count. Fatal Cases 4 and 5 which follow illustrate thrombocytopenic purpura occurring in *Bartonella bacilliformis* anemia.

Case 4

A S, an 18 year old farm helper, referred his disease to a traumatic accident on the dorsal surface of the right foot, which bled constantly. A local physician diagnosed gangrene of the foot. Careful interrogation, however, disclosed that this patient had been living for three months in an area where Carrion's disease is endemic and three days before receiving the foot wound, he had experienced general malaise and fever. He continued to work despite this symptomatology plus polydipsia and anorexia. After the accident, he noticed purpuric spots in the skin, epistaxis, bleeding of the gums, and a bloody discharge through the wound of the foot. On March 16, physical examination disclosed a well developed and well nourished, slightly jaundiced male, with many purpuric spots in the skin, bleeding of the gums, marked anemia, and petechial hemorrhage in the conjunctiva. Lymph nodes, of 5 to 15 mm, were palpable in the inguino-cervical, axillary, epitrochlear and cervical regions. The blood pressure was normal, the pulse 130 and the respirations 42 per minute. Over the first interosseal space on the right foot, there was a contusive wound 2 cm long and 1 cm deep with irregular borders, surrounded by an ecchymotic area of about 4 cm in diameter without signs of inflammation. Many other nontraumatic ecchymotic areas were spread over the body, especially on the anterior wall of the thorax. Coagulation time was thirteen minutes and bleeding time twenty-four minutes. Cultures for other bacteria besides *Bartonella bacilliformis* were negative. The peripheral blood had 0.97 red blood cells, 3,500 white blood cells and the differential was 56 neutrophils, 2 monocytes and 42 lymphocytes. There were 2 orthochromatic normoblasts and 1 plasma cell per 100 white blood cells. There was marked anisocytosis, poikilocytosis and anisochromia (table 1A). There were 50,000 platelets. No bartonellae were found in the red cells; nevertheless, Carrion's disease was diagnosed. The patient was given coagulants, fluids and anti-tetanic sera. He died on the second day of his admission. The gross pathologic diagnoses were terminal pulmonary edema, multiple petechial and ecchymotic hemorrhages, ecchymotic wound of the right foot and Carrion's disease. The stained smears of the spleen had many *Bartonella bacilliformis*.

This case illustrates a fatal thrombocytopenic purpura during a severe *Bartonella bacilliformis* anemia.

Case 5

M H, a 17 year old farm worker, after spending a month in a locality where Carrion's disease is endemic, on April 15, 1939, noticed fever, malaise and profuse sweating, symptoms which continued on the following days. The patient became anemic, slightly jaundiced and was brought into the hospital in a very critical condition on April 10, with convulsions, marked mental confusion, followed by a loss of consciousness. He appeared to be a well-nourished, well developed, seriously ill boy with a very marked anemia. There were many tiny petechial hemorrhages in the conjunctiva, pulsation of the arteries of the neck, functional murmurs over the precordium, and a slight yellow discoloration of the skin and sclerae. The pulse was 104 per minute, the blood pressure 120 over 70, the respirations were shallow, regular and 23 per minute. Examination of the spinal fluid on admission showed albumin 0.09 Gm per cent, glucose 0.44 per cent, urea 0.25 per cent, chlorides 0.4 mg per cent and 1 lymphocyte per cu mm. The Pandy reaction was negative. Typhoid and paratyphoid agglutinations were negative. The red blood count was 0.765 millions/cu mm (table 1A).

The patient continued with insomnia, a very annoying pulsating feeling in the head and ears, cramps in the epigastrium and right upper quadrant of the abdomen. The anemia increased and the general condition of the patient failed. The slight subicteric color of the sclera and skin disappeared and the icteric index became normal. No bartonellae were found in the red blood cells. The lymph nodes of the neck, inguinal and epitrochlear regions became enlarged. The fever oscillated between 36 and 40°C. On April 18, vomiting and headaches appeared with cough, rhonchi and crepitation of the lungs and on the April 22 many pinpoint purpuric spots were seen in the skin and conjunctiva. The patient became dyspneic and died on May 23. Autopsy showed the following prominent features: hydropericardium of nearly 1.5 liters, extensive petechial hemorrhages in many organs, such as the lungs, liver and spleen, external and internal hydrocephalus. *Ascaris lumbricoides* were found in the intestine.

This case illustrates a fatal recurrence of anemia due to thrombocytopenic purpura while the bartonellae were disappearing from the erythrocytes.

"CRITICAL STAGE"

The term "critical stage" of bartonella bacilliformis anemia has been applied to the period of transition in which the organism suddenly disappears from the red cells.²⁹⁻³⁵ The mechanism of this change is controversial, but it is a fact that within a few days the bartonellae may disappear from the peripheral erythrocytes. The hematologic signs of this transition are as follows: (1) A change in the form of the bartonellae from a bacilliform to a coccoid form (originally described by Barton³ in a report published from Lima in 1908) occurs with the appearance of sphere, hour glass, pear shape and granule forms. These are the coccoid bartonella. (2) Decrease in the number of the parasitized erythrocytes and in the number of bartonellae on each erythrocyte. (3) An increase in the erythrocyte count. (4) A reduction in the indirect hyperbilirubinemia to normal. (5) An increase in the number of reticulocytes. (6) A decrease in the macrocytosis, later in the disease the erythrocytes regain normal size and even have a tendency to microcytosis. (7) A lymphocytosis, the monocytes and eosinophiles reappearing. (8) A shift of the polymorphonuclear series to the "right," a characteristic which persists during the rest of the disease.

Clinically, corresponding with this transition, the fever disappears, the subicteric tinge of the skin and sclera disappear leaving an intense earthen gray pallor. With the prompt rise in the number of erythrocytes the symptoms of anemia, such as fainting, dizziness, tinnitus, etc., disappear, as well as the hemic heart murmurs, the blood pressure rises. The patient appears to be convalescent. However, this sequence of events does not always occur, for clinical improvement may not parallel the disappearance of the bartonellae from the erythrocytes. There may be an increased severity of the clinical course of the disease, which is due to intercurrent infections, or to an atypical course of the disease itself. Occasionally, there is clinically an increased severity of the disease, coexisting with the favorable hematologic findings of the critical stage, despite the fact that there is no evidence of intercurrent infections. In these cases, one finds fever, vomiting, tachycardia, insomnia, delirium and psychomotor irritability. This occurred in Case 6, which terminated fatally.

Case 6

J. M., an 18 year old female cook, lived for four months before becoming ill in an area where Carrion's disease is endemic. On October 6, 1939, she developed a headache followed by a chill, fever, malaise and profuse sweating. Despite the persistence of these symptoms, the patient did not stay in bed, the chills did not recur but the fever was continuous. She developed anemia and a slight yellow discoloration of the skin. On admission to the hospital on October 18, 1939, she appeared well nourished and well developed but was markedly confused mentally. She had severe anemia, slight jaundice, pronounced pulsations of the arteries of the neck and epigastrium, very dry skin, hemic murmurs over the precordium. The blood pressure was 115 over 70. The pulse was 120 per minute, the respirations were regular and superficial, 20 per minute. On October 20, the red count was 1.8 millions, hemoglobin 7.8 grams per cent, the leukocytes 6,080 (table 1A). The red blood cells showed a few bacilliform and coccoid bartonellae. No lymph nodes were palpable. The patient's condition rapidly failed, there was continuous vomiting and diarrhea, rigidity of the muscles of the neck, insomnia, motor excitability and headaches. She developed a deep coma progressively, nystagmus with marked increase in muscular tonicity of the neck and extremities. She had negative tendon reflexes and no Babinski response. A Cheyne-Stokes respiration

developed. The blood cultures were negative on several occasions for bacteria other than *Bartonella bacilliformis*. The detailed information of findings at the autopsy have been reported extensively elsewhere.⁵ No definite complications could be found.

An unusual fatal, short failing, hyperthermic course of the disease is illustrated in this case without apparent intercurrent infection. At the time the bartonellae were disappearing from the erythrocytes, the patient developed symptoms frequently found in cases with intercurrent salmonella infection.

It is not known whether the bartonella infection itself is responsible for death in these cases. The interaction between the bartonellae and the reticulo-endothelial system has been studied extensively.⁴⁰⁻⁴⁵ The bartonellae are found in large num-

FIG. 7

Leukocytosis occurring before death in case with *Bartonella bacilliformis* anemia complicated by amebic colitis.

bers in the phagocytic cells, such as the Kupffer cells of the liver, littoral cells of the spleen and of the lymph nodes, indicating clearly that the activity of the bartonellae is centered in the reticulo-endothelial system (figs 8-12).

Intercurrent infections may develop in these patients during the critical period of the anemia when there appears to be a lowered resistance of the host to invading organisms harbored in the gastrointestinal tract. These organisms frequently produce a fatal septicemia. In these cases the symptoms are bizarre and confusing. There is usually a rise in the temperature, tachycardia, diarrhea, dysentery, psychomotor excitability, followed shortly by death. There is a sharp leukocytosis with shift to the left in the polymorphonuclear series and a fall in the number of reticulocytes and normoblasts. This is well illustrated in figure 7, complicated by amebic colitis. Blood cultures are very helpful in determining the complicating organism. In this series of 30 cases, intercurrent infections were detected in 15, of whom 3 developed malaria which was promptly controlled by quinine therapy.

FIG 8

Large splenic blood sinus containing many nucleated red blood cells. The large dark littoral cells contain *Bartonella bacilliformis*. Giemsa stain $\times 580$.

2 out of 3 died with typhoid fever, 2 died of a *Salmonella schottmulleri* infection, 3 died with amebic colitis, and in 3 cases the necropsy examination suggested an anaerobic septicemia due to an undetermined organism.

FIG 9

Colony-like masses, each composed of innumerable *Bartonella bacilliformis*, in littoral cells lining a small splenic sinus Giemsa stain $\times 1275$

In 9 fatal cases, no bacterial or parasitic intercurrent infections were demonstrated. Peripheral collapse occurred in 1 patient who died, and thrombocyto-

PATHOGENESIS

Bartonella bacilliformis anemia is a hemolytic anemia in which the destruction of erythrocytes is dependent on the presence of *Bartonella bacilliformis* on the

FIG 12.

Section of the liver showing large Kupfer cells, which contain erythrocytes, nucleated red blood cells, and small aggregates of *Bartonella bacilliformis* Giemsa stain $\times 570$

erythrocytes The rate of destruction of the erythrocytes and the increased bilirubinemia¹⁵ are directly proportional to the number of parasitized erythrocytes ¹⁵ The anemia is macrocytic in type with signs of increased blood formation young

granulocytes, polychromatophilia, reticulocytosis and nucleated red cells. Hypochromia is a frequent finding but did not occur in several cases of this series (table 1). There is increased urobilinogen excretion in the feces. Hurtado et al.¹⁵ have shown that the fragility of the erythrocytes is normal in this disease. There are no spherocytes and enlargement of the spleen clinically does not occur in the cases without intercurrent infections.^{7, 13} Hemoglobinuria does not occur. An early suggestion was that the bartonella bacilliformis anemia was "Addisonian" anemia. Guzman-Barron⁴⁶ demonstrated the presence of Castle's principle in the gastric secretion, and careful hematologic studies¹⁵ have shown that the anemia is normoblastic and not megaloblastic and is accompanied by marked reticulocytosis. Histologically there is evidence of erythrocyte destruction in the reticulo-endothelial system as the Kupffer cells, littoral cells of the spleen and lymph nodes and other phagocytes appear filled with bartonellae and erythrocytes (figs 8-12).

PROGNOSIS

Bartonella bacilliformis anemia has a severe prognosis, due mostly to the frequency of intercurrent infection produced by varied organisms from the gastrointestinal tract. The host's defenses, already lowered by the bartonellosis, are overwhelmed by the subsequent infection.

In 30 cases studied in this series, 22 died, a mortality of 73 per cent. Fifteen of these cases had intercurrent infection, and of these, 11 died with septicemia of gastrointestinal origin. In a group of 15 cases without evidence of any concurrent infection, 9 died. In only 2 cases (Cases 3 and 5) could the death be explained by the virulence of the infection and the intensity of the anemia. Case 5 apparently died of a thrombocytopenic purpura with 440,000 erythrocytes. In the remaining 7 fatal cases the intensity of the anemia was not severe enough to explain the fatal course, the severity of the disease apparently being due to the bartonella infection itself.

TREATMENT

At present, there is no specific therapeutic agent which acts against the bartonella bacilliformis and the treatment used is largely symptomatic. A great deal of therapeutic effort has been directed toward stimulating the bone marrow. This is of dubious importance in cases without any complication, as the main problem in bartonella bacilliformis anemia is not the formation of red cells but the destruction of erythrocytes. The reticulocytosis is sufficient evidence of regeneration. Case 1 in this series without specific treatment or marrow stimulation showed an extraordinary degree of erythrocytic regeneration, this is seen in every case without intercurrent infection. The sudden transition occurring naturally in the course of the disease with disappearance of the bartonellae from the red cells may give the fallacious impression that a given drug or a treatment is responsible for such change. There is some evidence that liver extracts¹⁵ may accelerate the erythrocyte regeneration.

Blood transfusions appear to be indicated, however, up to the present this method of treatment has been used only occasionally. This is largely due to the

prevailing theory³⁵ that the crisis of the anemia with the disappearance of the bartonella bacilliformis from the red cells is due to the immunity of the red cells toward the bartonellae. Blood transfusion, according to this theory, will alter the immunity since the donor cells are supposedly more susceptible and so more apt to be parasitized. This is not acceptable, as the erythrocytes have never been known to have immunologic activity. The immunologic changes which occur in the host in the critical stage produce the changes both in the shape and in the clearance of the bartonellae from the erythrocytes. This is supported by the fact that the anemia does not recur in the course of the disease, even if fatal intercurrent infection occurs.¹⁴ Small blood transfusions of 300 to 400 cc. used in a very few cases with severe anemia and thrombocytopenia in my experience have proved to be a life-saving procedure. Unfortunately, larger amounts of blood were not available to test any of the patients included in this series. The other main objective in the treatment of bartonella bacilliformis anemia should be the prevention of intercurrent infection. Penicillin has lately been reported in a small number of cases to produce good results in the treatment of the disease.⁴⁷⁻⁵⁰ Further studies are necessary to evaluate the action of this drug. In the future, studies should be directed toward the control of the bartonella bacilliformis, as well as the prevention of intercurrent infection.

DISCUSSION

A severe hemolytic anemia may occur during the invasive stage of Carrion's disease. The pathogenic organism, bartonella bacilliformis, is found in the erythrocytes and on the cells of the reticulo-endothelial system. It has been previously stated that bartonella bacilliformis anemia occurs at any stage of Carrion's disease.^{2, 31 et al.} However, there are no proven cases in which this anemia has occurred except in the invasive stage of the disease. Anemias which occur later in the pre-eruptive and eruptive stages, were found in a previous study¹³ to have a different etiology and different morphologic and clinical characteristics. The anemias without bartonellas in the erythrocytes are due to intercurrent infections, hemorrhages, thrombocytopenic purpura or other causes. Recurrences of bartonella anemia did not occur in these series of patients even in cases with fatal intercurrent infections. This is another important fact against the concept³⁵ that blood transfusions should not be given to these patients because of the danger of reinvasion of the erythrocyte by bartonellae. On the contrary it seems from this study that these patients will be greatly benefited by repeated blood transfusions from 600 to 1000 cc. as a supportive therapy against the bartonella infection and the anemia. With the disappearance of bartonellae from the erythrocytes, which occurs during the natural course of the bartonella infection, the red cell hemolysis ceases and there is a spontaneous prompt recovery.

The transition period in which the bartonellae suddenly disappear from the erythrocytes in the circulating blood is characterized by a very low resistance of the host to secondary infection. This accounts for a considerable proportion of mortality in this disease, as is illustrated by 11 deaths occurring in 12 septicemic cases. In only 2 cases (Cases 3 and 5) in which the erythrocyte counts were ap-

proximately 5 million/cu mm could death be attributed to the severity of the anemia. In all the other cases the severity of the disease was due to the bartonella infection or to intercurrent infection and could not be related to the intensity of the anemia.

SUMMARY

Bartonella bacilliformis anemia (Oroya fever) is a febrile hemolytic anemia with distinguishing clinical and hematologic characteristics. It occurs as an infrequent clinical form during the invasive stage. The onset is variable with or without chills, followed by a moderate temperature which does not parallel the intensity of the anemia. Hemorrhages, petechial spots, epistaxis may occur and are due to thrombocytopenia. Clouding of the sensorium and delirium are rather uncommon. There is a generalized lymphadenopathy but no splenomegaly.

The anemia is macrocytic and frequently hypochromic with signs of intense blood formation: young granulocytes, polychromatophilia, reticulocytosis and nucleated red cells. The reticulocytosis may increase to 50 per cent. The pathognomonic sign of the disease is the presence of *bartonella bacilliformis* on the erythrocytes. The leukocyte count varies, slight leukocytosis is not uncommon but marked leukocytosis is extremely rare in cases without intercurrent infections. There is a shift of the polymorphonuclear series to the left, characterized by the presence of myeloblasts, myelocytes and metamyelocytes. The anemia is normoblastic and not megaloblastic. It is hemolytic and the destruction of erythrocytes is dependent on the presence of *bartonella bacilliformis* on the erythrocytes. There is no spherocytosis and the fragility of the erythrocytes is normal. Histologically there is evidence of erythrocyte phagocytosis in the cells of the reticulo-endothelial system, the Kupffer cells, the littoral cells of the spleen and the lymph nodes.

The disappearance of the bartonellae from the erythrocytes occurs in a very few days and is called "critical stage" of the anemia. The hematologic changes of this transition are as follows: a change in the shape of the bartonellae from the 'bacilliform' to 'coccoid' form before complete clearance will take place, an increase in the erythrocyte count, reduction in the indirect hyperbilirubinemia to normal, increase in the number of reticulocytes, reversion to normocytosis, lymphocytosis, reappearance of monocytes and eosinophiles, a 'shift to the right' of the polymorphonuclear series. Corresponding with the clearance of bartonella from the erythrocytes, the symptoms dependent on the anemia as well as the fever disappear. Clinical improvement, however, may not parallel the clearance of bartonellae because of intercurrent infections or an atypical course of the bartonellosis itself.

Bartonella bacilliformis anemia has a very severe prognosis, due largely to the occurrence of intercurrent infection by enteric organisms. The treatment today is largely symptomatic as there is no specific agent against the bartonellae bacilliformis infection.

It is suggested that the prognosis may be improved by the use of adequate blood transfusions and the prophylactic use of antibiotics to control intercurrent in-

fection At present there is no specific agent against bartonella bacilliformis anemia

CONCLUSIONS

1 Bartonella bacilliformis anemia (Oroya fever) is a type of hemolytic anemia in which the pathogenic organism of the disease is found in the circulating erythrocytes and in the cells of the reticulo-endothelial system

2 Bartonella bacilliformis anemia is macrocytic, frequently hypochromic and occurs only during the invasive stage of Carrion's disease and does not recur in the course of the disease Other anemias which develop later have different clinical and hematologic characteristics

3 The transition period in which the bartonellae suddenly disappear from the erythrocytes depends on immunologic changes of the host toward the bartonella infection

4 The prognosis of bartonella anemia is very grave, as is indicated by a mortality rate of 73 per cent in this series of 30 cases This very severe prognosis is largely due to intercurrent infection which occurred in 50 per cent of the cases studied The most severe prognosis was found in cases with septicemias from enteric organisms, as indicated by 11 deaths out of 12 cases

ACKNOWLEDGMENT

I wish to acknowledge my indebtedness to the attending physicians of Dos de Mayo, Arzobispo Loaiza, San Bartolome and the Maternity and Children's Hospitals in Lima, Peru, for permission to study the above patients I am also very grateful to Dr. Alberto Hurtado for facilities to do the hematologic studies in his Laboratory of Clinical Research, Arzobispo Loaiza, in Lima, and also to Doctors Charles Spurr, Eleanor Humphreys and Matthew Block for advice and criticism in the preparation of this manuscript

BONE MARROW OF NORMAL GUINEA PIGS

By ARTHUR SAWITSKY, M D ,* AND LEO M MEYER, M D

MARROW aspiration is a well standardized technic for the study of hematopoietic function in the human. The method has been applied to dogs¹ and cats² with success. In these animals bone marrow is obtained by aspiration of the iliac crest. The disadvantages of the aspiration method are loss of architecture and mixture of marrow and blood in varying unknown proportions. A great advantage is that frequent, serial examinations showing distinct qualitative differentiation of marrow cells may be obtained.³ No anesthesia is required, nor is any special aseptic surgical approach necessary.

Epstein and Tompkins⁴ reported values obtained both by microscopic section and supravital stain technic. We are presenting data on normal bone marrow as obtained by iliac aspiration, and comparing our values for bone marrow and peripheral blood with those of other investigators.

MATERIALS AND METHODS

The peripheral blood of 47 normal laboratory guinea pigs, both male and female, of unknown age and of weights varying from 268 to 640 Gm. was studied. Iliac marrow aspiration studies were made on 20 male guinea pigs of this group.

The technic for iliac puncture is essentially the same as that detailed in our study of normal cat bone marrow.² The animal is strapped to the table with dorsum presenting and extremities extended. The hair over the sacral area is clipped and the skin sterilized with a suitable antiseptic. Local anesthesia is not required. The anterosuperior border of the iliac crest is outlined with the fingers of one hand. A sterile 20 gage Quincke spinal tap needle about one and a half inches long is inserted through skin and muscle close to the iliac crest. Upon reaching the periosteum the needle is simultaneously rotated and pushed with a boring movement until the needle is firmly imbedded in bone. A sudden "give" is not experienced. The stylet is removed, a dry 20 ml. syringe is attached to the needle and about 0.2 ml. of marrow is aspirated. The needle and the attached syringe is then removed from the animal and a drop expelled on a clean glass slide. Nucleated cell and megakaryocyte counts are made with the technic used in counting the leukocytes of the peripheral blood. Thin films are drawn on several clean glass slides and stained with Wright's stain. Five hundred nucleated cells are counted and the percentages estimated, utilizing the classification of Vogel and his associates.⁵ The ilium may be fractured by the procedure, but a repeat aspiration can be made after ten to fourteen days.

From the Department of Therapeutics, New York University College of Medicine, New York, N. Y.

* Lederle Fellow in Hematology

OBSERVATIONS

The data obtained for the peripheral blood (table 1) are compared with those of other observers (table 2). The similarity indicates that the animals used in the present study were hematologically normal (table 1, Group II).

Bone marrow studies (table 3) indicated a wide range from 48 to 377 thousand cells per cu mm of bone marrow aspirated. The average marrow cell count was 191,200 per cu mm. Similarly, the number of megakaryocytes per chamber varied from 5 to 48 cells. The differential cell count showed a more constant pattern. The

myeloid series constituted 55.4 per cent, 28.3 per cent of which were segmented, and 15.8 per cent nonsegmented 'neutrophils.' This cell in the guinea pig, when examined with Wright stain, is not neutrophilic but pseudoeosinophilic. The cytoplasmic granules take a pale eosinophilic stain, are rounded and of fairly uniform size. In contrast, the true eosinophile has granules which are large, coarse, and somewhat irregular. Occasional heterophiles were also noted and have been included with the 'neutrophilic' group. Lymphocytes constituted 25.79 per cent of the marrow, 0.4 per cent of which had Kurloff cytoplasmic inclusion bodies.⁹ The erythroid series constituted 16.5 per cent of the cells counted.

species is shown in table 4. The cell counts of dog, cat and guinea pig agree fairly closely. The guinea pig marrow, however, shows a marked difference in its lymphocytic composition. These elements are significantly increased, more than in any of the other animals studied. The increased lymphocyte content is also seen in the peripheral blood of the guinea pig.

A comparison of bone marrow data with that of Epstein and Tompkins is shown in table 5. It may be observed that the interpretation of bone marrow data varies significantly with varying techniques. These differences are probably due to the inclusion of more peripheral blood in aspirated specimens than is obtained in biopsied material.

SUMMARY

1. A method is presented describing the technic for obtaining bone marrow from the iliac crest of the guinea pig by aspiration.
2. The cellular constituents in the peripheral blood and bone marrow of normal guinea pigs are presented.
3. Peripheral blood and bone marrow findings in guinea pigs are compared with those of other observers and with other animal species where the aspiration technic was used.

SEPARATION OF LEUKOCYTES FROM WHOLE BLOOD BY FLOTATION ON GUM ACACIA

By FRANCES SPEAR, B A , M S

A METHOD of separating leukocytes using serum albumen was described by Vallee, Hughes and Gibson.¹ An equally satisfactory and less expensive method has been developed in this laboratory using a gum acacia solution of proper specific gravity, hydrogen ion concentration, and osmotic pressure. Supravital studies of leukocytes separated by this method indicate that cells are viable and apparently undamaged. Preparation of solution

To 10 ml of distilled water in a 100 ml graduate (which has a stopper), 30 grams of gum acacia, and 30 ml water are added. The materials are mixed with a glass rod until solution is complete. Then 0.25 Gm of sodium bicarbonate are added. After mixing well, the glass rod is washed down with distilled water and enough water added to make 90 ml. The graduate is stoppered and heated in a water bath at 50 C for a few days. The solution is agitated at intervals and unstoppered occasionally to permit the escape of carbon dioxide. After a few days, the volume is brought to 100 ml with distilled H₂O. The pH is tested with a Beckman pH meter. If the pH is below 6.9, heating is continued.

When the solution has reached a pH of 6.9-7.2 through the combined effects of the original amount of sodium bicarbonate and continued heating, pilot tests are run to determine the combination of gum acacia and citrate-saline which will produce the best separation. Eight tenths ml of this gum acacia solution is mixed with 0.30, 0.35, 0.40, 0.45 ml of a 1 per cent sodium citrate in 0.5 per cent sodium chloride. After the solutions are thoroughly mixed, heparinized blood is added in the proportion of 1.5 ml blood to 1.0 ml of gum acacia saline-citrate mixture. With the exception of a few red cells which sink immediately, the blood floats. Tubes are spun at 500 r p m for ten minutes, and 3,000 r p m for thirty minutes. At the end of this time, in correct solutions, the red cells are at the bottom of the tube, and the white cells float at the interface of the layers of gum acacia and plasma where they may be easily collected with a capillary pipet.

The collected cells are placed in a small test tube with about twice their volume of 2 per cent citrate and shaken briskly to counteract the agglutination of platelets which was promoted by the colloidal gum acacia solution. To estimate the number of white cells present, the tube may be spun at 2000 r p m for five minutes, the supernatant fluid removed, and the cells resuspended in a measured quantity of 2 per cent sodium citrate. A WBC pipet is used for obtaining the number of cells per ml. The diluent used is a solution of brilliant cresyl blue 0.1 Gm, sodium citrate 3.8 Gm, and water 100 ml. The solution does not hemolyze the red cells which may be present and stains the white cells a pale blue. The total number of WBC present is estimated by multiplying the count per cubic mm $\times 1000 \times \text{ml of citrate added to cells in the last suspension}$.

From the Pathology Laboratory, Experimental Biology and Medicine Institute, National Institutes of Health, Bethesda, Md.

Cells at this point are examined supravitaly using Janus green-neutral red, or pinacyanol. They show Brownian movement and streaming of granules in polymorphonuclear leukocytes to be preserved. An occasional polymorphonuclear cell shows active movement. Lymphocytes show well stained mitochondria and rare neutral red vacuoles.

Six lots of gum acacia have been tried—two lots from E. R. Squibb & Sons and the others from B. R. Elk Co. They are fairly uniform. The specific gravity of the solution used ranged from 1.085 to 1.105. The pH after the addition of sodium bicarbonate was 6.9 to 7.2. Corrections for tonicity, specific gravity, and pH were obtained through the addition of that amount of saline-citrate solution showing the best separations in the pilot tests. The specific gravity of this mixture was 1.079, pH 7.3. Tonicity was measured by the freezing point as indicated on a Beckman thermometer when a sample of the solution was immersed in a Dewar flask filled with cracked ice and salt. The freezing point was $0.4 \pm$ when the freezing point of distilled water was taken as 0 degrees C.

SUMMARY

An inexpensive solution possessing the physiochemical properties necessary for separating leukocytes and erythrocytes on the basis of differences in specific gravity has been described.

EDITORIAL

THE USE OF FOLIC ACID ANTAGONISTS IN ACUTE LEUKEMIA

ACUTE leukemia remains the most important single problem in the field of hematology. Hopes that the disease may ultimately be controlled have recently been revived. It was found by several groups of investigators that folic acid and its conjugates at times seemed to accelerate the leukemic process.^{1 2 3} For this reason, the use of antagonists of folic acid suggested itself as a possible therapeutic measure and several of these have been prepared by Subbarow and his associates.⁴ By manipulation of the pteroyl glutamic acid molecule, as for example substitution of an NH_2 group for the OH group in the 4 position of the pteridine ring structure, an anti-folic acid preparation, 4-aminopteroyl glutamic acid or *aminopterin* is produced. Farber and his associates found that of the various folic acid antagonists which they tried in acute leukemia, aminopterin was by far the most potent. In a series of 16 cases of acute and subacute leukemia in children, these workers⁵ found that injections of aminopterin regularly resulted in remissions lasting for at least three months in 10 of the cases. The remissions were characterized not only by great subjective and objective improvement but by improvement in red count and in platelets, a virtual disappearance of primitive white cells from the blood, and a considerable improvement in the appearance of the marrow.

Farber's results, which were obtained in children, have not as yet been duplicated in adults. Personal communications from various centers where aminopterin and related drugs are being used indicate that good results have often been disappointing and that reactions such as hemorrhage, aplastic anemia, etc. are common. However, in our own series of 16 adults with acute and subacute leukemia, 4 patients with acute or subacute leukemia have developed clear-cut remissions characterized by subjective improvement, rise in red cells and platelets, disappearance of blast forms from the blood and a distinct improvement of the marrow picture. We have also had a clear-cut remission in one childhood case of two treated. Although these results may be considered as coincidental by some observers, the remission rate in Farber's series of 10 of 16 consecutive cases is far beyond the spontaneous rate of remission. We have been impressed, therefore, both in our own small series of cases and through examination of Farber's data, that the factor of spontaneous remission can be completely ruled out. If this is the case, then we may indeed be approaching the future control by chemotherapeutic means of what is now a practically hopeless disorder. The therapeutic effect of anti-pteroylglutamic acid preparations indicates that PGA may be one of the materials concerned in the growth processes of the white cells of leukemia. What is even more likely is that other enzymes more important than PGA are necessary for leukocytic growth. When these are found, anti-enzymes may then be discovered. Certainly further work along these lines is indicated.

Aminopterin and related drugs must be used with great caution for they

severe reactions of the mucous membranes and, in large doses, of the marrow as well. These chemicals should by no means be considered as cures, all they apparently do, even in the most favorable cases, is to keep the "flame" of leukemia under temporary control. However, the knowledge that even a little something can be accomplished in acute leukemia is very heartening news indeed, and a great stimulus for continued investigation.

ANEMIA

EFFECT OF XANTHOPTERIN ON CELL PROLIFERATION IN BONE MARROW CULTURES *E. R. Norris and J. J. Majnarich* From the Department of Biochemistry, University of Washington, Seattle, Washington
Am J Physiol 152: 175-178, 1948

Since 1936, Xanthopterin has been reported as curative of certain (nutritional) anemias and leukopenias in rats and fish. In 1940, xanthopterin was isolated from liver extract used in treating pernicious anemia. The present report concerns the effect of xanthopterin on erythropoiesis and leukopoiesis in bone marrow cultures *in vitro*.

The authors suspended bone marrow (rabbit, beef, sheep, rat, cat) in Tyrode's solution, added specified supplements (Tyrode's solution, folic acid, xanthopterin, normal human serum), and counted the various blood cells after three and six hours of incubation of the resultant mixture. They found that xanthopterin caused an increase in the rate of cellular proliferation of white cells, reticulocytes, and red cells, and that such an effect was optimal when the concentration of xanthopterin was about five micrograms per milliliter of suspension. The results obtained with xanthopterin and with normal human serum were of the same order of magnitude and were prompt. Folic acid, on the other hand, had no enhancing effect on proliferation of cells in these suspensions, suggesting, as the authors subsequently point out, that folic acid as such is unavailable to the marrow cells for growth. In a subsequent report dealing with nutritional anemia in rats, folic acid similarly was found to have an effect only after a lag period of several days, whereas the hematopoietic effect of xanthopterin was immediate (*Am J Physiol* 152: 179-182, 1948)
S. E.

XANTHOPTERIN IN RAT ANEMIA PRODUCED BY SULFATHIAZOLE *E. R. Norris and J. J. Majnarich* From the Department of Biochemistry, University of Washington, Seattle, Washington
Am J Physiol 152: 179-182, 1948

Anemia was produced in rats by feeding a purified diet augmented with 1 per cent sulfathiazole. The rats were then divided into three groups (with corresponding controls), and treated with xanthopterin or pteroylglutamic (folic) acid. The effect on the blood values was studied.

Group 1 These rats received 100 micrograms of xanthopterin daily for five days. There was an immediate and marked rise in red cells, hemoglobin, and hematocrit, which did not occur in the controls. A peak was reached, and then the blood values began to fall rapidly to their pretreatment ranges.

Group 2 These rats received single injections of xanthopterin (25, 50, or 100 micrograms) or synthetic pteroylglutamic acid (100 micrograms). The control group, which received no injections, died in seven days. Xanthopterin-injected rats showed a prompt rise in red cells, reticulocytes, white cells, and hematocrit, the rise being greater the greater the dose of xanthopterin. Rats receiving pteroylglutamic acid also showed a rapid rise in all blood elements, but there was a delay period of three to five days before this rise began.

Group 3 These rats received, by a single injection, either 100 micrograms of xanthopterin, or 300 micrograms of pteroylglutamic acid (this amount contains the same weight of pteridine as 100 micrograms of xanthopterin). Again, there was a rise in all blood values, but whereas the rise with xanthopterin was immediate, that with pteroylglutamic acid followed a lag period of one to three days.

It is suggested as a result of these experiments and similar results *in vitro* with bone marrow culture

(*Am J Physiol* 152 175-178, 1948), that xanthopterin can be utilized directly by the bone marrow in hematopoiesis, whereas pteroylglutamic acid cannot be utilized as such, but must be altered in form before it can affect hematopoiesis. It is strange that, in contrast, fragmentary experiences with xanthopterin in pernicious anemia suggested that it was of no value in the dosages employed (*South M J* 40 46-55, 1947), although, as is well known, pteroylglutamic acid is highly effective

SE

OBSERVATIONS ON THE ANTIANEMIC PROPERTIES OF VITAMIN B₁₂ T D Spies, R E Stone, and T Aramburu From Northwestern University at Hillman Hospital, Birmingham, Alabama *South M J* 41 522-523, 1948

Crystalline vitamin B₁₂ was administered by single intramuscular injection to two patients with pernicious anemia, two patients with nutritional macrocytic anemia, and one patient with nontropical sprue. Five of the patients received six micrograms of the material, the sixth, 15 micrograms. Within three to five days after the injection, the patients felt better and stronger, the soreness and burning of the tongue disappeared, and there was objective clinical and hematological improvement. Reticulocytosis (twelve to twenty-two per cent) occurred by the fifth to ninth day, and a rise in red count and hemoglobin followed. Although bone marrow examinations were done, no details are given in this brief report. There was also no extended followup.

This report confirms similar experiences in three patients with pernicious anemia following single injection of three to 150 micrograms of vitamin B₁₂ (*West, Science* 107 398, 1948). It is possible that this material isolated from potent liver extracts, may be the essential substance required for pernicious anemia.

SE

OBSERVATIONS ON THE HEMOPOIETIC RESPONSE OF PERSONS WITH TROPICAL SPRUE TO VITAMIN B₁₂ T D Spies, G G Lopez, F Milanes, R L Tola, and B Culver From the Northwestern University Departments of Nutrition and Metabolism, Calixta Garcia Hospital, Havana, Cuba *South M J* 41 523-525, 1948

In two patients with typical tropical sprue, the administration of eight micrograms of crystalline vitamin B₁₂ intramuscularly was followed within three days by marked subjective and objective improvement (mouth and tongue symptoms relieved, strength increased), as well as by a rise in the various blood elements, with reticulocyte peak in each case on the eighth day. No data beyond the eighth day of treatment are given.

SE

HIGH SERUM ACETYLCHOLINE CONCENTRATIONS IN PERNICIOUS ANEMIA AND THEIR REDUCTION BY EFFECTIVE THERAPY J E Davis From the Departments of Physiology and Pharmacology, University of Arkansas School of Medicine *Am J Dig Dis* 15 52-55, 1948

In dogs, the continued injection of acetylcholine produces a hyperchromic anemia which responds to antipernicious-anemia therapy, and the injection of derivatives of acetylcholine in dogs may produce central nervous system changes resembling those found in human pernicious anemia. The author, having developed a bio-assay method for the determination of the amount of acetylcholine in serum, measured the serum acetylcholine in five patients with relapsed pernicious anemia, two patients with remitted pernicious anemia, six normal individuals, and six individuals with secondary anemias (lymphosarcoma, leukemia, sickle-cell disease). The following results were obtained. It was found that the normal level of acetylcholine in serum ranged from 6.6 to 8.2 micrograms per 100 cc of serum, the level in secondary anemias was the same, but in relapsed pernicious anemia, levels of 15 to 33 micrograms per 100 cc were obtained. When specific treatment of these latter patients was instituted (liver extract, stomach extract, or pteroylglutamic acid), there was a marked reduction in the serum acetylcholine to normal levels within four to seven days.

It is speculative, whether the aberration in serum acetylcholine is fundamentally related to the occurrence of pernicious anemia. The author suggests the possibility that something produces an excess of acetylcholine in the serum, which in turn depresses or arrests erythropoiesis within the marrow, resulting in the disease. Actually, he points out, the serum cholinesterase in pernicious anemia is normal or only

slightly decreased, and in remitting pernicious anemia the cholinesterase may actually fall even further, whereas in normal and leukemic individuals, pteroylglutamic acid causes a rise in serum cholinesterase. It is possible, therefore, that perhaps the effect of antipernicious-anemia medicaments is to raise the level of cholinesterase in the blood cells rather than the serum (for this there is some evidence), that a fall in acetylcholine results from this, and that, with the fall, erythropoiesis reverts toward normal. These speculations are still tentative and, of course, do not suggest the basic cause for the alterations in the serum levels of acetylcholine or cholinesterase.

S.E

EFFECT OF FOLIC ACID AND LIVER EXTRACT ON SERUM AND RED CELL CHOLINESTERASE ACTIVITY *A M Kunkel, S Krop, and W C Wescoe* From the Pharmacology Section, Medical Division, Army Chemical Center, Maryland. *Am J Physiol* 152: 309-313, 1948

A diminution in the blood serum cholinesterase (ChE) has recently been reported in pernicious anemia, and it has been found that the administration of liver extract or pteroylglutamic acid in such cases was followed by a rise in the serum ChE, concomitant with the clinical and hematological improvement following such treatment. It has been suggested, therefore, that the role of liver extract or pteroylglutamic acid may be to cause an increase in serum ChE, which in turn is followed by an improvement in the anemia. The purpose of the present article was to test whether these materials actually cause a rise in serum ChE *in vitro* or *in vivo*.

Several experiments were performed:

1. Various amounts of pteroylglutamic acid and liver extract were added to normal human and dog plasma *in vitro*, and the mixture incubated at body temperature. The ChE levels of the plasma remained unchanged.

2. Dog plasma depleted of ChE by the use of diisopropyl-fluorophosphate (DFP), which irreversibly inactivates ChE, was similarly incubated *in vitro* with folic acid and liver extract. There was no rise in the ChE level.

3. An attempt was made to produce macrocytic anemia (with the accompanying decrease in ChE) in dogs by administration of acetylcholine and physostigmine. No anemia could be so produced, and, furthermore, there were no deviations of serum ChE levels in these dogs during this regimen, or after the addition of liver extract or pteroylglutamic acid.

4. Four dogs were given DFP, so that their plasma ChE level was much reduced. Two were followed without further therapy, to a third, 2 mg of pteroylglutamic acid were administered daily, and to the fourth, 2 units of liver extract daily. The recovery of plasma ChE to normal values was identical in all four dogs.

These data negate the suggestion that it is possible to cause an increase in the amount of serum ChE by the use of the antipernicious-anemia drugs, under the conditions of the experiments. They do not support the hypothesis that an acetylcholine-cholinesterase mechanism is concerned in erythropoiesis. Previous work had already shown that plasma ChE rises (in states of depletion) at a rate similar to the rate of regeneration of other plasma proteins. It seems probable, therefore, as the authors suggest, that the rise of plasma ChE in the successful treatment of pernicious anemia is the result, rather than the cause, of recovery.

S E

DEVELOPMENT OF APLASTIC ANEMIA DURING THE USE OF STREPTOMYCIN. REPORT OF TWO CASES *V F Dejke and J B Wallace* From Fitzsimmons General Hospital, U S A. *J A M A* 136: 1098, 1948

Streptomycin, according to the authors, has been used in some 900 patients in the literature. Of these patients, eight developed mild, self-limiting leukopenia, and one developed agranulocytosis, the outcome of which was unstated. Of 400 additional patients who received streptomycin in the authors' hospital, two developed aplastic anemia on the 79th and 95th days of treatment, respectively. In the absence of other etiologic agents for marrow involvement (other drugs, disseminated tuberculosis), the aplasia had to be attributed to the streptomycin.

The first patient, a 46 year old man with moderately advanced tuberculosis, received two grams of streptomycin daily for 79 days when his blood, previously normal, showed anemia, leukopenia, and neutropenia. Although the drug was discontinued, and various supportive measures used, the pancytopenia

topenia progressed, and the patient died 19 days later. Prior to death the white cell count was 800, with two per cent neutrophils (16 per cu mm), and red cells and platelets were much reduced. The marrow at autopsy was hypoplastic.

The second patient, a 27 year old man with moderately advanced tuberculosis, also received 2 grams of streptomycin daily, on the 95th day, pancytopenia was noted and progressed despite discontinuation of the medication. Marrow punctures showed hypocellularity of the marrow. The patient was still living at the time of the report.

S E

IDIOPATHIC HYPOPLASTIC ANAEMIA WITH BONE MARROW HYPERPLASIA *E S Mills* From the Departments of Medicine, McGill University and the Montreal General Hospital, Montreal, Quebec. *Canad M A J* 57 227-232, 1947

Three fatal cases of idiopathic anemia are described and autopsy findings in two of the cases are included. All three patients were males and each presented variants from the generally accepted pattern of so-called aplastic or hypoplastic anemia. One patient, who received 196 transfusions of 500 cc each, developed generalized hemosiderosis and brownish pigmentation of the skin. Remission occurred in this case after 12 years of illness, but death occurred soon thereafter as a result of pneumococcal infection.

Erythroid hyperplasia of the bone marrow in two of the cases is stressed and it is suggested that there is a maturation arrest in this disease due to deficiency of a factor other than that which is lacking in pernicious anemia.

In the author's interesting discussion of these cases is included a statement that the life span of a red cell is probably less than forty days. This statement should be challenged in view of the conclusive evidence from many laboratories that the life span of normal human erythrocytes is about 120 days.

L E Y

CLINICAL APPLICATIONS OF BONE MARROW EXAMINATION IN CHILDHOOD *I J Wolman, and B Dickstein* From the Children's Hospital of Philadelphia, the Department of Pediatrics, School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania. *Am J M Sc* 214 677-687, 1947

The authors have summarized the variety of information to be gained from sternal puncture. The methods of marrow aspiration in infancy and childhood are discussed, as well as normal and pathological cytologic findings. Attention is called to certain bacterial and protozoal infections and metabolic disorders in which diagnosis may be made by sternal aspiration.

C A F

TROPICAL MACROCYTIC ANAEMIA AND NUTRITIONAL MACROCYTIC ANAEMIA *H C Trowell* From the Mulago Hospital Medical School, Kampala, Uganda, South African. *J M Sc* 12 21-32, 1947

The response of sixty-three patients with severe anemia to therapy were studied by the authors. Of these, forty-three were macrocytic, twelve normocytic and two microcytic. Improvement following administration of iron and liver extracts was variable and not related to the red cell size. Crude liver extracts were more effective than highly concentrated liver, similar to the cases reported by Watson and Castle (*Am J M Sc* 221 514). The incidence of hookworm infestation (eighty per cent) was higher among these patients than in the general hospital admissions (forty-six per cent). The authors felt that tropical anemia differs from pernicious anemia in not showing a true megaloblastic anemia and in its response to liver therapy. They believe it represents several deficiencies rather than deficiency of the intrinsic factor.

C A F

RELATION BETWEEN SERUM PROTEIN AND HAEMOGLOBIN IN 324 INDIAN SOLDIERS *H Lehmann* From the No. 1 Detachment, Anaemia Investigation Team, General Headquarters, India. *Brit J Exper Path* 28 377-384, 1947

Previous surveys of the nutritional status of Indian troops indicated that there was more of a correlation between hemoglobin and serum protein levels than had been reported in similar studies in Europe and North America. Although several methods were used for determining serum protein, preference was given to the copper sulphate gravity method of Phillips et al. In these cases the hemoglobin determinations

tion seemed to be a more sensitive test for malnutrition than the determination of serum protein. In macrocytic anemias the dietary deficiency produces low serum protein levels. But in hypochromic or normochromic anemias due to a dietary deficiency in iron, the serum protein is not necessarily lowered.

O P J

NORMAL RED CELL SURVIVAL IN MEN AND WOMEN S T Callender, E O Powell and L J Watts From the Nuffield Department of Clinical Medicine, Oxford J Path and Bact 59 519-532, 1947

Blood was removed from four young women and two male medical students who belonged to group A and were Rh-positive. It was replaced by equal volumes of group O blood. By differential agglutination it was determined that the survival time was about 90-100 days in women and 110-120 days in men. The curve of decay of transfused cells was linear for men and slightly curved for women. Apparently blood destruction is greater in women. The estimated figure of 400 cc per month is much larger than that lost by menstruation alone.

O P J

HEMOLYTIC ANEMIA

PHYSIOLOGIC ICTERUS OF THE NEWBORN A Loewy and L W Freeman From the Department of Physiology, University of Chicago, Chicago, Illinois Am J Physiol 152 205-209, 1948

This paper suggests that the fat diet of the newborn infant plays a role in the rapid destruction of erythrocytes which gives rise to physiologic icterus of the newborn. The authors compared the serum bilirubin in cord blood at birth, with that in venous blood on the fifth day of life, in three groups of newborn infants: those on a routine diet (3.6 per cent fat), those on a low-fat diet (1.8 per cent), and those on a fat-free diet (0.03 per cent). (An attempt to evaluate a fourth group, on a 5.5 per cent fat diet, was unsuccessful because of refusal of feedings.) The average serum bilirubin at birth was 1.36 mg per cent. On the fifth day of life, high-fat babies showed 5.4 mg per cent of bilirubin, low-fat 4.2 mg per cent, and fat-free, 3.09 mg per cent.

Although these results are striking, they must be considered suggestive rather than conclusive, chiefly because of the small number of cases. Thus, there were ten children in the first group (3.6 per cent fat), although six showed a rise in serum bilirubin, four showed either no change or an actual fall. Of twelve children on the low-fat diet (1.8 per cent fat), eight showed the rise, but four showed no rise or a fall, and of nine children on the fat-free diet, six showed a rise, with the other three showing a definite fall. The procedure of averaging such small groups, as the authors themselves point out, may lead to erroneous results. There is, however, a trend, and it is not unlikely that sudden exposure of the newborn to a relatively high fat diet (fat is thought to be barred by the placenta) plays some role in physiologic icterus. That it is not the only factor is obvious.

S E

A NEW TYPE OF HEREDITARY HEMOLYTIC JAUNDICE WITHOUT SPHEROCYTOSIS R L Haden From the Cleveland Clinic, Cleveland, Ohio Am J M Sc 214 255-259, 1947

The author reports eight patients in two families with hemolytic anemia. The anemia was macrocytic, normochromic, accompanied by reticulocytosis, bilirubinemia, and splenomegaly. Fragility tests were normal and no spherocytes were seen. In two patients of one family, hemoglobinemia and hemolysis of erythrocytes on incubation was observed, but the Donath Landsteiner and acid hemolysis tests were negative. In the second family, stippled cells were consistently observed. The two groups show significant differences and neither fit into conventionally recognized types of hemolytic anemia. The author suggests that these are instances of congenital stromal defects of the erythrocytes.

C A F

ICTERE CHRONIQUE JUVENILE NON HEMOLYTIQUE AVEC REACTION DE HIJMAN VAN DEN BERGH INDIRECTE (DISREGULATION DU METABOLISME DES PIGMENTS BILIAIRES) (CHRONIC JUVENILE NONHAEMOLYTIC JAUNDICE WITH INDIRECT HIJMAN VAN DEN BERGH REACTION (FAULTY BILE PIGMENT REGULATION)) J Carols et A Paraf Revue d Hematologie - 267-282, 1947

The authors report the occurrence of jaundice in an eighteen year old boy, otherwise in perfect health.

This jaundice had existed since he was three years old. It consisted of a frank chronic mucocutaneous coloration, with occasional slight remissions. There had been no similar case in the family. The blood count was normal. Hemolysis of the red cells started in 0.48 per cent saline and was complete at 0.4 per cent. Rouleaux formation was normal. The average red cell diameter was 7.5μ and there was no spherocytosis. The blood group was O, Rh positive. The myelogram was normal (13 per cent erythroblasts). There were no bile pigments or bile salts in the urine. Urinary urobilin was 0.3 mg per litre, and 0.73 over twenty-four hours. Fecal urobilinogen (Watson method), 23 mg. Indirect blood bilirubin, 18.75 units, 1 c, 98.4 mg, and two days later, 24.60 units, 1 c, 98.4 mg. Cholemia was 10 mg per litre of serum. Finally, the urinary porphyrins were 40 per 1000. All liver function tests gave normal results. The authors discuss the nosological significance of this very definite observation and compare it with that of Dameshek and Singer (*Arch Int Med* 67:259, 1941) and of the hereditary jaundice of the rat studied by Mallay and Lowenstein. They think it is a nonhemolytic jaundice caused by an inborn error of the metabolism of the bile pigments with a kind of regurgitation of the indirect bilirubin.

J P S

RAPID TEST FOR THE DEMONSTRATION OF SICKLE CELLS AND ITS CLINICAL SIGNIFICANCE K. Singer and S. Robin. From the Department of Hematologic Research, Michael Reese Hospital, Chicago, Illinois. *J A M A* 136:1021-1025, 1948.

Sickling of susceptible red cells takes place only if the hemoglobin within the red cell is in the form of reduced hemoglobin. Oxygenating the reduced hemoglobin causes a reversal of the sickled cell to a normal biconcave disc. The various tests for sickling depend, correspondingly, upon reduction of the contained hemoglobin, and their speed and efficiency may be expected to vary directly (other things being equal) with their ability to cause this reduction.

The present authors utilize a culture of nonpathogenic bacteria (*B. subtilis*) to eliminate the oxygen in a blood sample, and thereby produce favorable and necessary conditions for sickling to occur. A drop of blood is placed upon a coverslip, a drop of the bacterial culture added to it, and the coverslip is placed upon a glass slide and ringed with paraffin. The preparation is then incubated at 37°C for five minutes and examined; if negative, it is incubated for an additional ten minutes and re-examined. Most positive tests appear within five minutes, and all within fifteen minutes, so that, according to the authors, those that are negative after fifteen minutes of incubation may be considered to be truly negative. The test does not discriminate between the severe sickle-cell anemia and the milder sickle-cell trait, since in both conditions the same abnormality of the red cell, a tendency to sickle under conditions of anoxia, is present.

This is the simplest of the reliable tests for the detection of sickling yet reported. The maintenance of an active culture of *B. subtilis* is discussed by the authors. Once started from agar slants, such a culture is carried with ease by day-to-day reinoculation of media, but refreshment from agar cultures at intervals is required. The speed of the results is of course a great asset.

S.E.

THE BASOPHILIC PROPERTY OF THE IRON-CONTAINING GRANULES IN SIDEROCYTES J. V. Dacie and I. Doria. From the Department of Pathology, British Postgraduate Medical School, London. *J Path and Bact* 59:684-686, 1947.

It has been known that some red corpuscles from patients with severe hemolytic anemia following splenectomy contain basophilic iron-positive granules. The present authors have shown that not all of the basophilic Romanowsky-positive bodies contain iron. This may be due to the fact that the iron content is too small for detection. Negative reactions for iron of basophilic stippling and Howell-Jolly bodies were obtained. In marrow from these patients, siderotic granules were found in nucleated red cells and in some instances they showed a perinuclear arrangement. It has been suggested that their appearance parallels that of hemoglobin because siderotic granules were absent from the more primitive nonhemoglobinized red cell precursor.

O P J

PATERSON-PLUMMER-VINSON SYNDROME IN A CASE OF FAMILIAL ACHOLURIC JAUNDICE L. Rau. *Proc Roy Soc Med* 40:271-272, 1947.

The authors present the coincidence, in a patient with familial spherocytic hemolytic anemia,

superimposed chronic iron deficiency (lip fissures, atrophic glossitis, koilonychia, hypochromic anemia) which included dysphagia and, on x-ray, spasm of the esophagus. The hypochromia responded to iron therapy, but there were no changes in the glossitis, nail changes, or esophageal picture, and reticulocytosis and increase in hypotonic fragility of the red cells persisted after the blood picture had lost its hypochromia.

The occurrence of both disorders in one patient must be very rare.

S E

THE MOTHER-CHILD INCOMPATIBILITY PROBLEM IN RELATION TO THE NERVOUS SEQUELAE OF HEMOLYTIC DISEASE OF THE NEWBORN *D F Cappell* *Brain* 70: 486-494, 1947

Kernicterus, the staining of certain parts of the brain by bilirubin in congenital hemolytic anemia, may be followed by permanent neurologic and mental changes in the surviving child. The author of this review presents the current concepts of erythroblastosis fetalis, and then discusses the possible relation of Rh incompatibility between child and mother, and subsequent mental difficulties in general.

Three forms of erythroblastosis are recognized: hydrops fetalis (with the child usually stillborn), icterus gravis neonatorum, and congenital hemolytic anemia. Kernicterus was noted only in those children who survived beyond the first few days of life; thus, in the stillborn with hydrops fetalis, kernicterus has not yet had time to occur, but if the newborn child with hydrops or severe icterus dies several days later, kernicterus is present. Kernicterus was not found in mild hemolytic anemias without jaundice, but only if jaundice was present. It was not possible to correlate the occurrence of kernicterus with the type of antibody found, the abnormality being found no matter which antibody predominated (agglutinins, blocking antibodies). In all infants surviving icterus gravis, evidence of nervous damage in later life was present in some 17 per cent of the cases.

The author does not agree that agglutination thrombi of red cells are responsible for the neurologic abnormalities (death and staining of nerve cells), and cannot suggest the reason for selective involvement of the cortex and basal ganglia.

With respect to the general question of the possible relation of mental deficiency in general to icterus neonatorum, the author reports on 200 mental defectives. He was unable to find a mother-child Rh incompatibility in various types of nonspecific mental defects as compared to cases of Mongolism, and as compared to normal children. This contradicts the work of Yannet and Lieberman (*J A M A* 130: 335, 1946), who found that, in a group of Rh positive mental defectives, there were twice as many Rh negative mothers as would be expected on a random basis, but Cappell points out how their figures were inadvertently weighted. It is generally agreed that there is a relationship between the occurrence of kernicterus and the severity of blood destruction (*V C Vaughn, J Ped* 29: 462, 1946), and that mental defects occur only if kernicterus has occurred (*M Creak, Arch Dis Childhood* 22: 180, 1947).

S E

VISCERAL LEISHMANIASIS COMPLICATED BY SEVERE ANEMIA—IMPROVEMENT FOLLOWING SPLENECTOMY *J H Birchenal, R F Bowers, and T A Haedicke* From the Medical and Surgical Services, Walter Reed General Hospital, Washington, D C *Am J Trop Med* 2: 699-709, 1947

An unusual case of kala azar refractory to a variety of agents and several courses of therapy is described, occurring in a twenty-three year old Negro soldier. In addition, a severe anemia with reticulocytosis and hyperbilirubinemia was present along with a leukopenia. Fifty-one liters of blood were given over a period of twenty-two months. Following removal of the spleen weighing 3050 gms., the patient made a recovery from the anemia and leukopenia and had no further symptoms of leishmaniasis. The organisms were recovered from the spleen at the time of the operation by hamster injection. The authors are anxious not to give the impression that splenectomy is indicated or necessary in most cases of kala azar, although in this instance of refractory disease complicated by hemolytic anemia it was particularly effective.

R S E

BLOOD COAGULATION AND HEMORRHAGIC DISEASE

QUANTITATIVE STUDIES ON THE COMPARATIVE ACTIVITY OF CALCIUM AND CHEMICALLY RELATED IONS ON THE COAGULATION OF BLOOD *M Stefanski and A J Quick* From the Department of Biochemistry, Marquette University School of Medicine, Milwaukee, Wisconsin *Am J Physiol* 15: 389-396, 1948

Amberlite IR-100, a phenol formaldehyde resin, is capable of removing calcium from blood serum without otherwise producing any changes in the blood. The authors utilized this material to study the effects of various concentrations of calcium, strontium, magnesium, and barium on blood coagulation. Blood was obtained from man, dogs, and rabbits, decalcified with the Amberlite, and stored on ice. The coagulation time of the decalcified blood was determined after addition of specified concentrations and amounts of the various ions. Thromboplastin was reduced to a minimum by the use of silicon-coated needles, syringes, and glassware.

It was found that coagulation did not occur until the concentration of calcium chloride in the blood was of the order of 0.0015 M . This is the actual level of calcium in the blood in the human body. Once this level of calcium was reached, there was a relatively wide range of concentrations in which coagulation occurred normally. A delay in coagulation did not occur until the concentration of calcium was reduced below one-half of normal. Above a calcium level of 0.004 M , the coagulation time of the blood became more and more prolonged.

Strontium behaved similarly to calcium in its ability to cause coagulation of decalcified blood, but was much weaker. Magnesium was found incapable of causing coagulation, except in the presence of thromboplastin, and then was weak in its action. Barium was incapable of producing coagulation even in the presence of thromboplastin. It was found, in this connection, that the presence of thromboplastin allowed coagulation at lower levels of calcium and strontium than when it was absent, and the more thromboplastin, the lower the requisite concentration of the calcium or strontium ion. Changes in calcium level in physiologic and pathologic states are never within the extreme ranges of alteration in the experiments, and are probably never sufficient to alter the speed of coagulation in the human patient.

S E

HEMORRHAGIC DIATHESIS IN HIROSHIMA, NAGASAKI AND AT BIKINI ATOMIC BOMB TEST. A. L. Copley. From the Laboratory of Cellular Physiology, Department of Biology, New York University, N. Y. C. J. Nat. Med. 137: 145, 1948.

It is known that petechial hemorrhages and thrombocytopenia occurred after the atomic bomb explosions, and that, in addition to thrombocytopenia, hyperheparinemia occurs after exposure of dogs to x-rays, and is in part responsible for the resultant bleeding tendency. The present author seeks to correlate the occurrence of hyperheparinemia and thrombocytopenia, with resultant hemorrhage, by pointing out that (1) heparin induces clumping of platelets, thereby producing platelet-agglutination *in vitro*, and thrombocytopenia *in vivo*, and (2) the injection of heparin in various animals induces not only petechiae but also white emboli (platelet-clump plus white blood cells), which also result in vascular damage. He suggests, therefore, that ionizing radiation may produce its hemorrhagic effect by inducing hyperheparinemia (mechanism unknown), the heparin then clumping platelets (thrombocytopenia plus petechiae) and causing white embolization (petechiae).

The observations upon which these suggestions are based—i.e., the effect of heparin on platelets, etc.—are as yet unconfirmed.

LEUKEMIA AND LYMPHOMA

EFFECTS OF RADIOACTIVE SODIUM ON LEUKEMIA AND ALLIED DISEASES. T. C. Evans, M. Lenz, C. P. Driscoll, and M. J. LeMay. Department of Radiology, Columbia University, N. Y. C. Am. J. Roentgenol. 54: 469-481, 1948.

Na^{24} (half-life 14.8 hours) was given orally in single doses of about 20 millicuries. The amount of radiosodium in urine was less than 10 per cent of administered dose. Cases treated included chronic myelogenous leukemia (7), subacute and acute leukemias (4), chronic lymphatic leukemia (4), acute lymphatic leukemia (2), polycythemia vera (1), sympatheticoblastoma (1). Case reports are presented for many of the patients. There was no radiation sickness. In chronic leukemia changes in the peripheral blood were similar to those following other types of irradiation. However, the therapeutic results were not superior to those with P^{32} or x-ray, and the short half life of the isotope would make its general use impractical.

C. F.

DISCUSSION ON CHEMOTHERAPY IN MALIGNANT DISEASE *A Haddow, E Paterson, I A Thomas, E W Rishes, E Boyland* Proc Roy Soc Med 41 45-51, 1948

This is a largely clinical discussion on recent attempts to influence malignant disorders by various chemical means. Included are short discourses on estrogens in carcinoma of the prostate, chloroethylamines (nitrogen mustards) in Hodgkin's disease, and urethane in leukemias.

S E

NITROGEN MUSTARDS IN THE TREATMENT OF HODGKIN'S DISEASE AND LYMPHOSARCOMA *M Sherry* From Sinai Hospital, Baltimore South Med J 41 118-129, 1948

Experiences are reported with the use of nitrogen mustard in the treatment of a small series of cases of lymphomatous disorders. The results duplicate those found in other centers: there was no effect in two patients with melanocarcinoma and two patients with lymphosarcoma, a fair response in a patient with giant follicle lymphosarcoma, and excellent responses in five of six patients with Hodgkin's disease. Relapse in the latter cases occurred within four months in most instances, although one patient was still in remission 11 months after treatment. It was noted that the lymphocytes in the blood typically became pale, granulated, deformed, and otherwise changed after nitrogen mustard, showing changes of noxious nature.

S E

THE TREATMENT OF BOECK'S SARCOID WITH NITROGEN MUSTARD: A PRELIMINARY REPORT *G E Snider* From the Veterans Administration Hospital, Fort Howard, Maryland South Med J 41 11-14, 1948

This short clinical report, admittedly preliminary and inconclusive, seeks to suggest that the use of nitrogen mustards may accelerate remissions in widespread sarcoidosis. Four cases are presented, in all of whom the diagnosis was established ultimately by node biopsy, and in all of whom there was involvement of eyes, lungs, nodes, and sometimes skin. Methyl-bis (beta chloroethyl) amine hydrochloride was administered in two courses one month apart, and the patients followed for signs of change. Marked retrogression of enlarged nodes, lung infiltrations, and ocular and other abnormalities occurred in the first three cases, beginning from two weeks to three months after initiation of treatment, the fourth case remained stationary.

The natural course of the disease makes evaluation of this and any similar short-term report most difficult, as the author himself points out. A complicating factor is the presence of tuberculosis in case 2, as demonstrated by sputum inoculation of a guinea pig, and it is at best questionable whether nitrogen mustards should be used in tuberculosis. It is true that many of the changes to normal were remarkable, but whether chloroethyl amine played a role in these changes cannot be deduced from the evidence presented.

S E

BOECK'S SARCOID IN CHILDREN *R J Reeves, G J Baylin, and P A Jones* From the Department of Radiology, Duke Hospital and Duke University School of Medicine South Med J 41 295-302, 1948

This is a review of thirteen children with sarcoidosis, aged from 9 to 14 years, in whom observation was made for periods as long as seven years. The authors point out that there are only twenty-one previously reported cases in the literature, and that the disease, although uncommon, is not rare in the young age groups.

S E

HEMATOPOIETIC TISSUES

ISOLATED CHROMOSOMES *A E Mirsky and H Riss* From the Laboratories of the Rockefeller Institute for Medical Research, New York City J Gen Physiol 31 1-6, 1947

Erythrocytes of the salmon, carp and fowl have been used as a source for obtaining isolated chromosomes. The procedure for the isolation of chromosomes was the first part of a method used by the authors to prepare a desoxyribose nucleoprotein complex-chromosin. The isolated threads showed a definite organization along their axis: a tightly coiled helix and at least two chromonemata. Since few of the

cells were in mitosis, the isolated chromosomes were liberated from interphase nuclei. This is additional evidence that chromosomes retain their individuality during interphase, or the so-called resting stage
OPJ

THE CHEMICAL COMPOSITION OF ISOLATED CHROMOSOMES *A E Mirsky and H Ris* From Laboratories of the Rockefeller Institute for Medical Research, New York City *J Gen Physiol* 31 7-18, 1947

Lymphocytes of the calf thymus are a convenient source for obtaining isolated chromosomes. The method of isolation was somewhat similar to that used for fish and fowl blood. By fractionation of the isolated chromosomes it was shown that 90 to 92 per cent of the mass was largely desoxyribose nucleohistone. The insoluble residue (or residual chromosome) contained a nonhistone, tryptophane-containing protein, 12 to 14 per cent ribose nucleic acid, and about 2 per cent desoxyribose nucleic acid. For years hematologists and cytologists have described basichromatin and oxychromatin. It now appears that these two chromatins differ chemically.

OPJ

EFFECTS OF EXPERIMENTAL CRYPTORCHIDISM UPON THE THYMUS, MEDIASTINAL LYMPH NODES AND ACCESSORY SEX GLANDS OF THE ALBINO RAT *J C Plagge* From the Department of Anatomy, University of Illinois College of Medicine, Chicago, Illinois *Anat Rec* 98 597-608, 1947

The use of cryptorchid animals made it possible to study the influence of the secretion of the interstitial tissue of the testis upon the thymus and mediastinal lymph nodes. Unlike the results obtained in castrated albino rats, there was no striking enlargement of these organs.

OPJ

THE CYTOPLASMIC BASOPHILIA OF BONE-MARROW CELLS *J C White* From the Department of Pathology, The British Postgraduate Medical School, Hammersmith, London *J Path and Bact* 59 223-234, 1947

There has been an increasing amount of evidence to substantiate the concept that cytoplasmic basophilia and a high ribonucleic acid content are characteristic of young and actively growing cells. White has contributed to this by applying Brachet's cytochemical test to bone marrow aspirations from six normal individuals and nineteen with various pathologic conditions. Ribonuclease abolished the basophilia of the cytoplasm and nucleoli in proerythroblasts and myeloblasts. In such cells a fine ring of nucleolus associated chromatin remained which was more deeply staining in the former. After nucleoli have disappeared in the more mature cells, distinct and deeply staining chromatin persists at their site. In pernicious anemia, hemocytoblasts, young normoblasts and young megaloblasts had a high content of cytoplasmic ribonucleic acid. The granular nature of basophilic cytoplasm was shown by the use of acid fuchsin to be due to the presence of numerous mitochondria.

OPJ

FURTHER OBSERVATIONS ON THE CHEMICAL CYTOLOGY OF MEGAKARYOCYTES AND OTHER CELLS OF HEMOPOIETIC TISSUES *G B Wislocki, H Bunting and E W Dempsey* From the Department of Anatomy, Harvard Medical School, Boston, Mass *Anat Rec* 98 527-538, 1947

Bone marrows from several rhesus monkeys and six guinea pigs were studied after applying various cytologic and histochemical techniques. Both the basophilia and metachromasia of megakaryocytic cytoplasm were abolished after digestion in a solution of ribonuclease. Although this was true for the rhesus monkey, it was not entirely so for guinea pig megakaryocytes, because they retained some metachromasia after exposure to the enzyme. The distribution of mitochondria seemed to be identical with that of the cytoplasmic objects with an affinity for sudan black. Blood platelets exhibited a faint basophilia and metachromasia. The presence in blood platelets of lipoidal particles, mitochondria and bodies reacting supravitaly with neutral red similar to those found in the cytoplasm of megakaryocytes reaffirmed Wright's theory for their origin. Further studies were also made on tissue eosinophils and basophils.

METACHROMASIA IN MAMMALIAN TISSUES AND ITS RELATIONSHIP TO MUCOPOLYSACCHARIDES *G B Wislocki, H Bunting, and E W Dempsey* From the Department of Anatomy, Harvard Medical School, Boston, Massachusetts *Am J Anat* 81 1-38, 1947

Metachromasia is of interest to the hematologist because certain blood cells possess that property of inducing chemical and chromatic changes when stained with suitable dyes. Wiskul and his associates have investigated this in tissue sections of material from rhesus monkeys fixed in four per cent basic lead acetate and stained with one half per cent toluidin blue. Some metachromasia is due to the presence of mucopolysaccharides but in other instances it may be referable to the presence of other nucleoproteins and substances of unknown composition. Tissue mast cell granules have a strong affinity for both toluidin and methylene blue. The metachromatic reaction was unaltered by exposure to hyaluronidase. These granules did not give the Baue reaction after digestion with saliva. The authors were unable to abolish the metachromasia present in metachromatic cytoplasm after exposure to ribonuclease.

AN IMPROVED METHOD OF STAINING TISSUES WITH SUPRAVITAL STAINING BLACK. *B. H. F. Stewart and G. B. Storey* From the Pathology Department, University of Liverpool. J. Path. and Bact. 53: 336-337, 1947

The authors have developed a new method for using Sudan black in differentiating various granules as seen in dry smears of normal blood. The results have been very consistent and better than those obtained previously. Such things as fixation in formaldehyde vapor and the use of a buffered solution containing phenol have improved the technique. Sheehan and Storey attribute a mordanting action to the phenol. In this connection it must be pointed out that another interpretation of the action of phenol is possible, namely that of lipophanerosis. The authors made the interesting comment that in certain blood diseases neutrophilic (polymorph) leukocytes do not contain sudanophilic granules. This will be described in a subsequent paper.

O P J

THE EFFECTS OF LEAD SALTS ON THE HEMATOPOIETIC AND HISTIOCYTIC SYSTEMS OF THE LARVAL FROG. *B. C. Barrett Jr.* From the Department of Anatomy, Western Reserve University, Cleveland, Ohio. Am. J. Anat. 81: 117-138, 1947

The effects of solutions containing 1 part lead salt to 40,000 parts water on the hematopoietic systems of larval bullfrogs was studied in 40 control and 143 test animals. Although both lead acetate and lead nitrate produced similar results, the action of the latter was more rapid. Among the first changes observed were those in the mature erythrocyte which became fragile and subject to fragmentation. There was a subsequent increase of immature erythrocytes and hemoblasts. Differentiation seemed to occur in the peripheral blood with the eventual formation of some spheroidal erythroplastids. The liver, which is not normally a hematopoietic organ in the tadpole, developed lymphogranulopoietic areas in the perportal connective tissue. In advanced stages of lead poisoning degenerating erythrocytes were present in the sinuses of the spleen. In this situation they remained unphagocytized because of toxic alterations in the histiocytes. Normally the intertubular mesonephric connective tissue of the larval frog is the chief hematopoietic center. This became rapidly depleted of its cellular elements and, for some unknown reason, eosinophilic myelocytes actually increased there.

INTERCELLULAR CEMENT AND CAPILLARY PERMEABILITY. *R. Chambers and B. W. Zettsch* From the Department of Biology, Washington Square College of Arts and Sciences, New York University, New York. City Physiol. Rev. 27: 436-463, 1947

This review of the basic anatomic physiology of cellular membranes—specifically the capillary wall—discusses fundamental rather than clinical interpretations of the problems of capillary tonus, permeability, and fragility. From the point of view of structure, three types of membrane may be discriminated: (1) one in which the cell itself determines the permeability of the membrane (e.g., the proximal tubule of the kidney), (2) one in which both the cell and an intercellular material determine the permeability (e.g., intestinal mucosa), and (3) one in which permeability of the membrane is determined exclusively or largely by the intercellular material. Into this last group the authors place the capillary membrane.

The capillary wall consists of endothelial cells plus an interendothelial cement elaborated by these cells, an endocapillary lining which seems to be an adsorbed layer of a blood protein, and a pericapillary sheath of connective tissue. With regard to the interchange of material between blood and tissue (i.e., permeability of the capillary), the interendothelial cement substance serves as the basic framework. It acts as an ultrafilter the selective properties of which depend directly on variations in its porosity.

Its porosity (and therefore the permeability of the membrane) is high, as compared with the permeability of the endothelial cells themselves, which is low. The porosity of the intercellular material may be affected by mechanical stretching, by chemical and pH changes of the surrounding medium, etc. This cement substance is thought to be produced by the endothelial cells, and to be in a constant state of usage and replacement.

The endocapillary lining seems to be an adsorbed layer of blood protein, probably albumin, which penetrates the porous interstices of the cement and helps reduce the pore size of the cement filter. In this way, it helps to reduce capillary permeability. The pericapillary sheath is a condensation of connective tissue which serves mechanically to support the blood capillary.

Changes may occur in any of the three components of the capillary and result in increased permeability. It is of interest that the variations in capillary permeability can be explained by changes in the nonliving components of the capillary wall: the intercellular cement, the endocapillary protein, and the pericapillary connective tissue sheath. The endothelial cell itself apparently often merely produces the cement substance. It is apparent, correspondingly, that it may be difficult to explain a given change in permeability on a single basis, and that it is unreasonable to assume a single permeability factor to account for fluid balance in the body.

This article discusses further the topography of the capillary bed, the roles of precapillary vasomotion and of hydrostatic and colloid osmotic pressures in permeability, the nervous control of capillary permeability, and the significance of various agents affecting capillary permeability. The manner of action of histamine, adrenal cortex, and various agents affecting capillary permeability, are discussed.

THE EFFECTS ON VENOUS ENDOTHELIUM OF ALTERATIONS IN BLOOD FLOW THROUGH THE VESSELS IN VEIN WALLS AND THE POSSIBLE RELATION TO THROMBOSIS. *J. F. O'Neill*. From the Department of Physiology, Harvard School of Public Health, Boston, Massachusetts. *Ann Surg* 126: 270-288, 1947.

An ingenious technic is presented for mounting flat segments of vein walls so that the inner coats of the wall can be stained and studied. Benzidine, which selectively stains red blood cells, was used to outline the vascular plexus in vein walls, and silver nitrate was employed in staining and studying the inner coats of vein walls.

Increasing endothelial desquamation was found in vein segments which were dissected free from all blood, lymphatic and nerve supply to the walls, but which were left unobstructed *in situ*. Despite the presence of raw, muscular surfaces, however, intravascular clotting seldom occurred, presumably because the velocity of blood flow was maintained. When blood flow was reduced by eighty to ninety per cent following the application of small metal clamps without isolating the vein from its bed, there was less resultant endothelial damage but slightly greater tendency toward thrombosis. When isolation and partial obstruction of vein segments were combined, there was a high incidence of intravascular clotting but it is acknowledged that further experience with this procedure will be required before firm conclusions can be drawn regarding the mechanisms involved.

CULTURE OF BONE MARROW *IN VITRO*. *A. Freschi and G. Astaldi*. Pavia, Italy, Tip. del Libro, 1946.

The Italian authors have assembled in a book the results of twelve years experience concerning bone marrow.

They studied in succession normal marrow, pernicious anemia, leukemia, and erythroblastosis.

In vitro, normal marrow loses its organic characteristics, immature granulocytes develop in a slow and restricted manner. During the course of this development, one may see a new generation of granuloblastic cells which are derived either directly from hemocytoblasts or possibly from pre-existing granuloblasts. Erythroblasts develop much more rapidly and completely than granulocytes to the orthochromatic stage or even after a reticular formation, arrive at the red anuclear globular stage. Very few immature erythroblasts develop to replace the elements which have evolved.

When after fifteen to twenty days the parenchymal elements have gradually disappeared the histiocytes develop and are soon transformed into a pure culture of fibroblastic elements.

In myeloid leukemia, one meets a similar evolution; the degree of development is no different; a different time of survival of the parenchymal cells is analogous.

In lymphoid leukemia the same time of survival and development of the fibroblastic cells is observed. One may note, in addition, morphologic modifications of the lymphocyte (the chromatin less thick, the protoplasm more diffused) and this would not be a matter of actual return to the most immature forms but the mere adaptation of the cells to a new environment. It is important to note that the histomonocytic cells observed do not ever result in lymphocytic elements; the matter concerns two separate developments, and the differences can only make themselves plain successively in the culture: the lymphocyte disappears when the histocytes are transformed into the fibroblasts which alone survive.

In acute leukemia, a new fact is obtained: the possible survival of parenchymal elements after a month of culture. Different in structure, the root cells of acute leukemia do not give rise to macrophages or to true monocytes, nor to fibroblasts. The extremely polymorphic elements which can take shape, although of histoid morphology, are of hemato-myeloblastic appearance but do not appear to form any cells of a normal grouping. The cells of acute leukemia are of the "pseudoparenchymal" type which doubtless explains their particular faculty for survival, though they do not evolve toward the fibroblastic state.

Thus chronic leukemia and acute leukemia appear to possess very different histogenesis.

The authors expect shortly to issue a classification of the leukemia. We limit ourselves here to a brief resume of the results of medullary culture in the leukemias which displays at the same time the interesting aspects and the actual limits of the method of study to which Liechi and Astaldi have devoted themselves.

THE EFFECTS OF EXPERIMENTAL HYPERTHERMIA AND RESTRAINT ON THE BLOOD AND HEMATOPOIETIC ORGANS OF THE ALBINO RAT. J. S. Latta and W. P. Nelson. From the Department of Anatomy, College of Medicine, University of Nebraska, Omaha, Nebraska. *Am J Anat* 62: 321-331, 1945.

The authors studied the effects of sustained fever on the blood values of white rats, and in a preliminary study they used as controls two animals which were untreated except for handling and one which was restrained but untreated. Quite unexpectedly the restrained animal showed marked changes. Hence the problem of determining what effects on the blood and blood-forming organs were attributable to hyperpyrexia alone arose. Albino rats were placed in a Kettering hypertherm and after rectal temperatures reached $103-104^{\circ}\text{F}$, they were maintained at this temperature for five hours. Blood samples were obtained from the tail. Both sustained fever and restraint produced a marked lymphopenia after the first hour. Neutrophils first increased then decreased moderately and finally increased again during the fourth and fifth hours of hyperpyrexia. In the case of restraint, neutrophils increased steadily to twice the absolute value in five to six hours. This increase was not sufficient to offset the lymphopenia in heat-treated animals. Consequently, a leukocytosis did not occur. Tissue studies indicated a relative marrow depression in hyperpyrexia and no evidence of a neutrophilic infiltration in various organs. The marked lymphopenia was accounted for in part by a failure of delivery and to a greater extent by degeneration and destruction of lymphocytes.

HEMATOPOIESIS IN THE EUROPEAN PLUTODONTID, *HYDROMANTES ITALICUS*, WITH REFERENCE TO PHYLOGENY. W. C. Barrett, Jr., From the Department of Anatomy, Western Reserve University, Cleveland. *Anat Rec* 98: 127-136, 1947.

Most hematologists are so engrossed with problems related to clinical hematology that not infrequently they forget about the vast and relatively unexplored field of comparative hematology. In the human, some disturbances of the hematopoietic organs may be recognized and classified according to the type, amount and distribution of hematopoietic tissue. Biologists have put somewhat similar information to an entirely different use. Knowledge that hematopoietic loci may be variously distributed in the organs of amphibia, and that they may be either lymphoerythropoietic or lymphogranulopoietic, has made it possible to determine the phylogenetic position of certain genera.

O P J

SHRINKAGE OF LYMPHATIC TISSUE IN RATS FOLLOWING INJECTIONS OF INSULIN. I. T. Zecker. From the Department of Pathology, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania. *Am J Physiol* 152: 267-270, 1948.

In view of the work of Selye with the alarm reaction, and of White and Dougherty with an interrelationship between adrenal cortex and lymph nodes, it was thought of value to see whether other agents known to affect the adrenal glands might lead to similar effects in the lymph nodes. Specifically, since insulin is known to stimulate the adrenal medulla by way of the sympathetic nervous system, would the same results upon lymphoid tissue occur following this endogenous release of epinephrine, as occur, for example, following an alarm reaction, or the injection of (exogenous) adrenalin?

The author injected one group of rats with epinephrine daily for three to seven days, and another group of rats with ascending doses of insulin daily for three to seven days. Other rats served as controls. The rats were then killed and their tissues weighed. With few exceptions, it was found that adrenal tissue enlarged after insulin or epinephrine, and that lymphatic tissue shrank after insulin or epinephrine.

The author postulates that various stimuli (e.g., injury, insulin) which cause discharge of adrenal medulla secretion, in so doing also cause slower but more sustained cortical activity (after injury, for example, the cortex enlarges, loses its lipids, and secretes its hormones). Hence, perhaps, the adrenal medulla is a link in the pituitary-cortex interrelationship, and, also, stimuli which affect this relationship may therefrom affect the lymph nodes.

Although no blood counts were done, mention is made of a previous observation that insulin produces lymphocytopenia and dissolution of cells in lymph nodes (Latt, J. S., and Henderson, J. W., *Folia haematologica* 57: 206, 1937), i.e., a reaction similar to that found by Selye following an alarm reaction, and by White and Dougherty following the injection of adrenal cortex.

S E

AN EXPERIMENTAL STUDY OF LYMPH NODE REGENERATION IN RABBITS *W. J. Furuta* From the Department of Anatomy, University of Illinois College of Medicine, Chicago, Illinois. *Am. J. Anat.* 80: 437-505, 1947

Although many reports have been made on the regeneration of lymph nodes, they have not been too careful in reporting the age of the animal, method of node removal and length of postoperative period. The results in the present article were obtained after a study of 270 specimens of popliteal nodes obtained by unilateral and bilateral excisions of 152 rabbits (three days to three and one-half years in age). Popliteal lymph nodes prior to fixation measured 8×12 mm. Supernumerary nodes were very rare. Regeneration, progressive differentiation of undifferentiated tissue, was optimum in incidence and quality in rabbits about one and one-half months old, thirty days postoperatively. This occurred from lymphoreticular tissue in perinodal areolar tissue. One of the most outstanding findings was that senile nodes may be activated by lymphoid vaccine so that there is perhaps no complete loss of structure and function.

O P J

AGE CHANGES IN LYMPH NODES *F. A. Dineen* From the Department of Morbid Anatomy, University College Hospital, Medical School, London. *J. Path. and Bact.* 59: 575-591, 1947

Over three hundred lymph nodes from deep cervical, inguinal, bronchial, mesenteric and axillary groups were obtained from 150 autopsies. Three groups of subjects were equally divided among those derived from (a) accident cases, (b) acute medical and surgical cases, and (c) chronic disease cases. With respect to structural differences and response to aging, lymph nodes may be divided into two groups—superficial and deep. There is a difference between cortical and medullary reticulum (argyrophil fibers) in both. In the cortex the meshwork is larger, more open and polyhedral in shape than in the medulla. Superficial nodes undergo retrogression at puberty. This is characterized by a shrinkage of lymphoid tissue on the capsule rather than the hilum which results in a cup-like structure filled with connective tissue. Germinal centers of the superficial nodes are fewer in number, smaller in size and they possess smaller pale centers than those of deep nodes. Although there is a diminution in size of germinal centers of deep lymph nodes from puberty onward, they can still be found at the age of eighty. Retrogressive changes in deep lymph nodes are unlike those in the superficial group in that there is a gradual retention of the fetal type of node.

O P J

contraction and emptying of the postulated stored blood in human adults. He injected blood containing labeled red blood cells (labeled with radioactive phosphorus according to a technic of the author) into 5 healthy men, and took blood samples in 10 and again in 15 minutes after the injection. The subject was then made to do severe muscular work, and two further blood samples taken, the first at 25-30 minutes, the second at 27-39 minutes. All samples were subjected to radioactivity determinations in a Geiger-Müller counter. It had previously been shown by the author that the radioactivity of the blood remains constant for at least 60 minutes after such an injection, hence, the volume of the circulating red cells could be measured by the radioactivity of the blood. Presumably, if any reservoir of blood was present which responded to the severe muscular exercise, discharge of red cells from this reservoir would change the radioactivity of the circulating blood.

Nylin found, actually, that there was no significant change in the specific radioactivity of the blood after exercise within the time studied. For all the patients, the mean circulating cell volume before work was 2,408 ml, as compared with 2,471 ml after work, and the mean circulating total blood volume before work was 4,934 ml, as compared with 4,855 ml after work. Since the amount of the red cells was unchanged, it was concluded that there was no reservoir which empties red cells into the circulation after work. This result is in contrast with the work of Bancroft (in dogs), and with the commonly held opinions that epinephrine contracts the spleen and thereby increases the numbers of circulating red cells. If verified, these conclusions would be of great theoretic importance.

OCTOBER, 1948

This issue is the fifth part of the George Minot Anniversary Volume

HISTORICAL NOTES ON BLOOD PLATELETS

By LEANDRO M. TOCANTINS, M.D.

ON MARCH 7, 1842, at a session of the "Académie des Sciences" of Paris during an account of studies on the microscopy of blood, Donné¹ stated in clear terms that there existed in the blood, red and white globules and little globules ("globulins"). There seems to be no earlier record of the recognition of the platelet as a formed element of the blood. Later, in his book "Cours de Microscopie," Donné² repeated and amplified his original description. Although his interpretation of the origin of the "globulins" (the lymph) was erroneous, the substance and manner of his opening statement indicates that he had clearly recognized the existence of a distinct morphologic element (fig. 1). Signs of awareness of the presence in the blood of forms other than white and red cells were evident before Donné. In Hewson's and Andral's³ works, references are made to certain white globules and bodies distinct from leukocytes and red corpuscles but of uncertain nature, occurrence and identity.

At about the same time as Donné, Zimmermann described certain bodies which he believed were the precursors of red blood cells. He called them "Elementarbläschen" and remarked on their tendency to gather in clumps. Zimmermann⁴ appears to have been among the first to use anticoagulants in the cytologic study of blood. He bled a horse and collected the blood in a solution of 6 per cent magnesium sulphate, equal parts of blood and solution. In this mixture he found what were undoubtedly platelets.

Among the first attempts to attribute the origin of platelets to other blood elements is the work of Schultze⁵ (1865). He had observed in normal blood small elements which he considered to be of protoplasmic nature. These had a strong tendency to clump and form granular masses ("Kugel") which he did not consider identical with Zimmermann's "elementar blaschen"; he thought they resulted from the destruction of white corpuscles. Schultze's hypothesis was corroborated in 1872 and subsequent years by Riess,⁶ who maintained that during anemias and cachectic states, the white corpuscles fragment and give rise to smaller corpuscles which he called "zerfallskörperchen" (disintegration bodies), analogous to the "Kugel" of Schultze, but differing from Zimmermann's "Elementarblaschen".

Throughout the third quarter of the past century one finds, here and there, what were probably platelets described as bacteria.⁷ The morphologic variability of

From the Division of Hematology, Department of Medicine, Jefferson Medical College, Philadelphia

platelets, depending on the conditions of collection and observation of the blood, was perhaps the reason for regarding them as extrinsic matter, peculiar to certain pathologic conditions. In 1873, Vulpian⁸ noted the presence in the blood of colorless corpuscles having the properties of sticking to the cover glass and accumulating in clumps. In the same year, Ranvier⁹ observed in the center of the fibrinous network that appears during coagulation of blood, granulations with tinctorial characteristics different from those of leukocytes and erythrocytes. He advanced the

PHYSIOLOGIE — *De l'origine des globules du sang, de leur mode de formation et de leur fin*, par M. AL. DONNÉ (Extrait par l'auteur)

(Commissaires, MM. Magendie, Flourens, Dumas, Milne Edwards, Payen)

« Il existe dans le sang trois espèces de particules : 1° les globules rouges ou sanguins proprement dits, 2° les globules blancs qui n'ont été bien connus que dans ces derniers temps, 3° les globulins du chyle.

• Les globules rouges sont plats dans toutes les espèces de sang; ils sont circulaires dans le sang des mammifères, et elliptiques dans celui des oiseaux, des poissons et des reptiles.

FIG. 1. EXCERPT FROM DONNÉ'S REPORT BEFORE THE PARIS ACADEMY OF SCIENCES (1842)

FIG. 2. DRAWINGS BY WILLIAM OSLER ILLUSTRATING THE ORGANISMS HE OBSERVED IN THE VENULES OF FRESHLY KILLED RATS (1874)

view that these masses probably determine the coagulation of blood, very much in the same way as the crystal of a salt brings about the crystallization of a saturated solution of that salt.

In 1874, Osler¹⁰ pointed out that the 'granular masses' of Schultze result from the agglutination of small bodies which occurred as single units in the circulation. He demonstrated, and his illustrations clearly showed for the first time, that these granular masses occurred as single elements in the circulating blood (fig. 2), and came together when the blood was shed. Osler's observations were carried out in the venules of recently killed young rats, and mark the time when the platelet be-

gan to be held, not as an artefact or a by-product of a change in shed blood, but as a normal constituent of the circulating blood itself

A few years later, Hayem¹¹ pointed out that "il existe dans le sang de tous les vertébrés des petits éléments qui ne sont ni des hématies, ni des globules blancs". He, however, believed that the elements represented primitive red corpuscles that had not gone beyond a certain phase in their evolution, for this reason he called them "hematoblasts". Hayem attributed to the hematoblast a double function: it was a coagulation accelerating agent ("le sang porte dans son sein un hémostatique puissant")¹² and it played a role in the regeneration of blood, a conclusion based on his observations on changes in the platelets after hemorrhage and in acute diseases. Some of Hayem's first studies were concerned with the evolution of the red blood cells in the blood of oviparous and viviparous vertebrates. It was these and subsequent studies that led him to consider the platelet as a precursor of the red blood cell. Without the breadth of his training and experience it was, and is, difficult to follow his views. Today, the available evidence makes it unlikely that such a relationship between platelets and red blood cells exists, as claimed by Hayem. The prevailing view of the origin of platelets renders it improbable that a body that arises from fragmentation of the cytoplasm of megakaryocytes may later be transformed into a red blood cell. Moreover, the morphologic features of the precursors of red blood cells are now well established and differ substantially from the platelet.

The existence of the platelet as a distinct element in blood within the vessels was further confirmed by Bizzozero^{13, 14}. He seems to have been the first to observe the platelet circulating in the blood of living animals. He stressed that the "granular masses" of Schultze were neither residues of white corpuscles which were destroyed before or after collection of the blood, nor granulations of fibrin, as thought by Ranvier. The masses were derived from special morphologic elements pre-existing in the blood, which he called "plattchen". Bizzozero was probably influenced by the expression "blaschen" (globule, vesicle) that had been previously used by Zimmerman. It was Bizzozero¹³ who established securely the foundation for the present day conception of the platelet as a distinct element of the circulating blood, ("Einen neuen Formbestandteil des Blutes") (1882), and indicated the part it plays in thrombosis. Before his work, the white thrombi were considered to be made up principally of leukocytes¹⁵. By a number of ingenious experiments, Bizzozero demonstrated that the white portion of these thrombi consisted almost exclusively of platelets, gradually accumulated at a point in the vessel where the wall had been injured or the circulation obstructed. Once accumulated in a mass, "in vivo" or "in vitro," the platelets underwent changes in appearance, became unusually sticky, a phenomenon he designated as "viscous metamorphosis". Bizzozero's observations had the merit of having been made on the circulating blood of a living animal (fig. 3). Osler's observations were made on the vessels of dead animals, it was perhaps because of this fact that, at the time of his report, Osler⁷ was not quite clear in his mind whether these bodies might be bacteria. The title of his paper "An Account of Certain Organisms Occurring in Liquor Sanguinis"¹⁰ carried that implication. The expression "plaquette" was not used by Bizzozero¹⁶ in his

work until 1891, and seems to have been introduced by Hayem¹⁷ in 1883. Bizzozero originally referred to these bodies as 'petites plaques' or simply 'plaques' (fig 3). The English word "platelet" does not seem to have been used until later in the 19th century. Osler¹⁸ was among the first to translate Bizzozero's expression "Blut Plattchen" as "Blood Plates" although he did not consider it a good descriptive word. Other expressions used to designate these elements were "blood plaques,

En examinant avec un objectif à immersion le contenu de ces vaisseaux (veines ou capillaires) on arrive à ce résultat surprenant, qu'en réalité à côté des globules rouges et des globules blancs circule un troisième élément morphologique (fig 2). Il est représenté par de petites plaques ← très pâles de la forme de disques à surfaces parallèles ou, plus rarement, de lentilles ovales ou rondes, d'un diamètre égal au tiers ou à la moitié de celui des globules rouges. Ces plaques sont toujours incolores et circulent dispersées irrégulièrement entre les autres globules, ne montrant point de préférence pour la partie centrale plutôt que pour la partie périphérique du courant. Ordinairement elles sont isolées les unes des autres, ce qui n'empêche pas cependant que souvent on ne les trouve réunies en groupes plus ou moins grands. Cette agglomération est déjà

FIG 3 ILLUSTRATION AND TEXT IN BIZZOZERO'S PAPER, DEMONSTRATING THE EXISTENCE OF PETITES PLAQUES IN BLOOD WITHIN THE VESSELS OF LIVING ANIMALS (1882)

'disklets,'¹⁹ third corpuscles,²⁰ ²¹ 'fugitive corpuscles,' 'fugitive discs,' 'invisible colourless discs'^{22, 23}

Among those who lent their support to the discovery of the new morphologic element was William H. Howell who died in February 1945, after a career in physiology extending over a half a century. His first paper corroborating and extending Bizzozero's observations was published in 'Science' in 1884.²⁴ One of his last papers proposing the lungs instead of the bone marrow as the principal source of platelets appeared in 1937.²⁵

Bizzozero's monograph gave rise to much opposition from the pupils of A. Schmidt²⁶ and Lowit²⁷ who adhered to the theory that the bodies designated as

"Plättchen" by Bizzozero were derived from fragmentation of leukocytes. Much of the disagreement and contradiction in papers that followed Bizzozero's may be attributed to technical difficulties that, even today, try the patience of those engaged in the study of platelets. The many shapes and arrangements presented by these bodies have confused some investigators, whose opinions rested mostly on morphologic evidence obtained 'in vitro'. Bizzozero also departed sharply from

the view held by Schmidt²⁶ that the fibrin ferment originated from the destruction of leukocytes. Among the opponents of Bizzozero's ideas were Weigert,²⁸ who attributed the findings of the Italian investigator to artefacts resulting from vessel compression, circulatory disturbances and the anesthesia employed. Bizzozero countered these objections by repeating and confirming his own observations on the *intact* vessels of the wing of a living unanesthetized bat.¹⁶

Wooldridge²⁹ on the basis of experiments with incoagulable bloods, especially after the injection of peptone, believed that platelets were simply a precipitate of

the globulin portion of the plasma ('Globulin Plattchen ') and not a distinct element of the blood Lowit²⁷ supported Wooldridge's contention and brought out much evidence against the existence of the platelet. The idea that the platelet, as such, does not exist in the blood is still encountered in modern texts,³⁰ a repercussion of the observations of Wooldridge. The observations of Bizzozero, were later confirmed and extended by Eberth and Schimmelbusch³¹ and Laker² while studying the circulating blood in the vessels of living dogs and other mammals. Eberth and Schimmelbusch further pointed out that in blood within the vessels, the corpuscles usually run in the center of the stream, the periphery being made up of plasma alone (fig. 4). Slowing or stasis of the circulation is followed by

FIG. 5. TABLE GIVING THE RESULT OF THE FIRST ACCURATE PLATELET COUNTS BY HAYEM (1)

of blood generally accepted today as representing the normal does not differ significantly from that found by Hayem.

From a consideration of the facts brought out by Bizzozero, Hayem¹³ concluded in 1882 that the platelet thrombus played an important part in the arrest of bleeding, and that a decrease or absence of platelets should result in disruption of the mechanism of hemostasis. A year later (1883) Krauss³³ reported in one form of hemorrhagic disease, purpura hemorrhagica, a diminution in platelets followed by an increase, after the hemorrhage ceased. In 1887 Denys³⁴ confirmed this finding and later Hayem³⁵ actually counted only 62,000 platelets per cmm of blood in a young patient with purpura. Hayem³⁵ ³⁶ also drew attention to the large size of the platelets and the soft quality and poor retractility of clots formed from the blood of these patients, and attributed these defects to the decrease or absence of platelets.

Hand in hand with the efforts of observers of the time in affirming or denying the existence of the platelet as a distinct element, went attempts to trace the source of the elusive bodies. Many held the view that they originated either from nucleated red cells or from the red cells themselves. Engel³⁷ derived the platelets from the nuclei of normoblasts and Wlassov³⁸ and Bremer³⁹ believed they came from disintegrated erythrocytes, and did not accept them as constituting a third element of the blood. The bodies examined by Wlassov and Bremer must indeed have been by-products of disintegration of erythrocytes, resembling platelets only in form, the same bodies were later studied by Arnold⁴⁰ in intravascular clots and in blood allowed to stand outside the body for several hours. These ideas were corroborated and in part amplified by Muller,⁴¹ Determan,⁴² Maximow,⁴³ and Schwalbe.⁴⁴ Antagonists of the theory that the platelet was derived from the destruction of red blood cells were Petrone,⁴⁵ Sacerdotti⁴⁶ and Dominici,⁴⁷ who criticized the view of Arnold and adherents of his theories, and pointed out that their conclusions rested on artefacts from preparations of dried smears of blood. This recurring source of confusion was partly due to the fact that differentiating stains were, at the time, not generally available. It was not until the polychrome Romanowsky stains and azure dyes began to be widely used, that it was possible to separate the red-to-violet azurophilic granules of the platelet from all sorts of granular material in and out of cells. Dominici⁴⁷ introduced a new, and what proved to be a partially correct, conception of the origin of the platelet. He held that platelets were 'organites,' that is, formed elements liberated by cells and lacking a nucleus. As the 'mother cells' of the platelets, he described mononuclear cells with a protoplasm distributed in long pedicles which, when broken off, made up the platelets. It is possible that this conception influenced the work of Wright.⁴⁸ It differs from his theory in only one respect. Wright showed that this fragmentation took place from the cytoplasm of the megakaryocyte.

Two other workers of the Italian school came close to the solution of the problem of the origin of platelets. While studying the formation of the red blood cells, Foa and Salvioli⁴⁹ observed that the giant cell of the bone marrow, first described by Bizzozero⁵⁰ in 1869, and later (1890) called megakaryocyte by Howell,⁵¹ fragmented into many colorless hyaline bodies. Foa and Salvioli thought these cell fragments were the precursors of the red blood cells. This view and Hayem's ideas

overlap at certain points, for Hayem thought that platelets (which we now know were the cell fragments observed by Foa and Salvioni) were the precursors of erythrocytes ('hematoblasts')

Bizzozzero's conception of the platelet as an independent element of the blood was soon carried even further by those who claimed for it cellular characteristics common to most cells. Deetjen⁵² using osmic acid fixation, believed he had shown that platelets had a nucleus and protoplasm. By special technics he also claimed to have demonstrated that platelets send out protoplasmic processes similar to the pseudopods sent out by leukocytes, a fact confirmed by Wright,⁴⁸ who saw some of the pseudopods retract. The observations of Deetjen were supported by Deckhuysen⁵³ and Koppsch.⁵⁴ These concepts influenced Deckhuysen perhaps to regard the mammalian platelet as homologous to the nucleated spindle cells of invertebrates and oviparous animals, which behave, when the blood is shed, very much

1906

FIG. 6. COPY OF A COLOR PLATE IN WRIGHT'S ARTICLE (1910)

Megakaryocytes bordering the sinusoids of the bone marrow and extending processes into the blood current, fragmenting giant platelets

like the mammalian platelet. This is why Deckhuysen called these cells in the lower species, *thrombocytes*.

Vassale⁵⁵ and Foa and Carbone⁵⁶ were among the first to find platelets in the spleen. Foa⁵⁷ differed from Vassale regarding their presence in the lymph nodes, Foa considered the hyaline bodies of the lymph nodes to be fragments of mononuclear cells and not true platelets.

Wright's discovery in 1906⁵⁸ that the megakaryocyte of the bone marrow gave rise to platelets by fragmentation of its cytoplasm was the next important development (fig. 6). All those present when Wright exhibited his preparations agreed that his demonstration was quite convincing.⁵⁹ His views, however, were taken up slowly by European investigators. Part of the reason for this might have been the relative lack of clarity of the illustrations accompanying his first contribution (1906).⁵⁸ His arguments were strengthened by a later report in which the documentation was clear and striking.⁴⁸ With but a few exceptions, one by one the leading histologists of the world have come to accept his views.

It was probably due to Wright's interest and stimulating influence that W. W.

Duke became interested in the problem of platelets and their relation to abnormal bleeding. Duke came under Wright's influence early in his career, as a house officer in the Massachusetts General Hospital. The role of the platelet in spontaneous hemostasis, first clearly visualized by Hayem, was convincingly shown by Duke⁶⁰ when he proposed the "bleeding time" of the skin as a test of a general tendency to bleed. Duke showed that there existed a close correlation between the number of platelets in the blood and the duration of the bleeding time. Apparently for the first time, abundant clinical as well as experimental evidence was gathered in support of this relationship. Duke was responsible, perhaps more than any other contemporary author, for strengthening the concept of the role and importance of platelets in disorders of hemostasis.

THE ROLE OF ALLERGY IN THE PATHOGENESIS OF PURPURA AND THROMBOCYTOPENIA

By FREDERICK W. MADISON, M.D.

ALLERGY by one term or another has been recognized as an etiologic factor in purpura since the earliest descriptions of that disease. Until very recently however, the intangible nature of both allergy and purpura, the multiplicity of potential etiologic factors, and the lack of exact knowledge of the pathologic changes in the latter state have made determination of the relative importance of allergy virtually impossible. Even now it is very difficult to evaluate the role of the allergic mechanism with accuracy. To attempt such an evaluation, it is essential to review briefly the chronologic development of the knowledge of the existence of allergic factors in the pathogenesis of purpura. It is likewise essential to define terms, for, as Piney¹ has recently stated, "Among the confused chapters in hematology, purpura is the most confused."

For a number of years it has been our custom to use the term purpura to indicate vascular changes only.² These vascular changes are characterized by reversible alterations of as yet unknown character in the walls of the smaller vascular radicles which make possible the escape of whole blood from the vascular bed. Such escape may occur more or less spontaneously (petechiae, nontraumatic ecchymoses) or it may be induced by increasing the intravascular pressure (e.g., tourniquet test,³ Gothlin test,⁴ etc.) or by decreasing the extravascular pressure (suction test,⁵ capillary resistometer,⁶ etc.). Artificial induction of petechiae is the most satisfactory criterion for the diagnosis of purpura at the present time, although lack of standardization of technics and variability of the vascular changes have made interpretation somewhat difficult. Other tests^{7, 8} are more complex and less suited to routine clinical use, but are useful for supplementary or corroborative purposes. After comparative trial of the various tests, we have come to rely almost entirely upon a simple tourniquet test done with a pneumatic arm band at 100 mm. of mercury (unless the systolic pressure is below that level, in which case it is correspondingly reduced) and maintained for 8 minutes, unless extravasation of blood is so marked as to cause excessive infiltration of cutaneous tissues, in which case it is stopped at a shorter time. A representative area 2.5 cm. in diameter is chosen, and the petechiae in it are either counted or recorded graphically. More than ten easily seen petechiae within the circle is regarded as a positive test, and the petechiae in excess of that number may be regarded as a quantitative expression of the test. A positive test is interpreted to indicate the presence of purpura, but a single negative test is not adequate to rule it out because of the variable nature of the vascular changes.

Purpura in this sense may and does most frequently exist alone.² It may, however, coexist with or be complicated by defects in the coagulation or clot retraction mechanism of the blood (hypoprothrombinemia, thromboplastin deficiency, thrombocytopenia, fibrinogenopenia) in which cases the combination of inadequate blood coagulation and "leaky" vascular walls produces an hemostatic error of such magnitude as to cause serious blood loss. From a clinical standpoint, it would seem to be much simpler to separate the vascular and hematologic factors and, at least for the purpose of etiologic studies, to consider thrombocytopenic purpura as purpura with thrombocytopenia or as two coexisting abnormalities. The im-

portance of this dual approach is apparent in tracing the chronologic development of the knowledge of the etiology of these states

One of the earliest discussions of the etiologic factors in vascular purpura is to be found in the "Opera Omnia" of Riverius. According to the English translation of Culpeper⁹ (1678), he stated "But there is one Symptome proper and peculiar to a pestilential feaver which doth not happen in other Feavers, viz, Purple Specks or Spots on the whole body which the Italian Physicians name Peticulæ or Petechia, and these Feavers which have these symptoms are commonly named Purpuratae or Petechiales and sometimes they are very large and possess whole members and then the parts appear tainted with redness which in a few hours oftentimes vanisheth away, and then returns again and are commonly called Ebullitions of the blood There do appear in other Diseases, spots very like unto those aforesaid, but springing from a far different cause, viz, from the over thinness of the blood, which being exagitated by the heat or the expulsive faculty does sprout forth of the Capillary Veins into the Skin These spots are wont for the most part to appear in such as have some Flux of the Blood, because the Blood in such is more thin and watery and also in Splenetick persons, and in such as have the Jaundice and old obstructions of the Bowels, and in all such who are apt to fall into a Cachexy " Interpreted in modern terms, Riverius suggested that infections, blood diseases, malignancy, diseases associated with splenomegaly, jaundice and cachexia were of etiologic importance in purpura The reference to the redness which in a few hours oftentimes vanisheth away, and then returns again" may well be construed to represent the earliest recognition of an etiologic mechanism which might now be regarded as of allergic nature

The next important addition to the list of causative or associated factors came a hundred years later when Werlhof¹⁰ in 1735 described the classical case of an 'adult girl, robust, without manifest cause, attacked toward the period of her menses with a sudden severe hemorrhage from the nose and about the neck and on the arms, spots partly black, partly violaceous or purple " It is well to recall that no knowledge of thrombocytopenia or other coagulation defect existed in the eighteenth century but, regardless of the presence or absence of such defect, this would seem to be the first recognition of endocrine factors in the etiology of purpura In the same period Hornung¹¹ suggested that clinical purpuras be divided into simplex, febrile and scorbutic types, thus apparently recognizing in his third group what we now know to be deficiency states as important etiologic factors

The most tangible early suggestion of the relationship of allergy to purpura is found in the classification of Willan¹² (1808) which included five types purpura contagiosa, purpura simplex, purpura senilis, purpura hemorrhagica and purpura urticans It is of interest to note that this classification may have been the origin of the term purpura hemorrhagica which has continued in general usage to the present time A few years later Schonlein¹³ (1837) reported the symptom complex which has borne his name and in which purpura occurred in association with multiple joint involvement The recent report of Montgomery¹⁴ of the incidence of purpura in rheumatic fever has re-emphasized the importance of this symptom group In 1868 Henoch¹⁵ described a similar case and recorded the addition of severe ab-

dominal pain and intestinal hemorrhage Six years¹⁶ later he added several similar cases and the syndrome characterized by purpura and abdominal pain has since borne his name Many years later Glanzmann,¹⁷ in reviewing these syndromes, suggested that the basic mechanism in all of the cases of both the Schonlein and the Henoch types was of allergic nature and suggested that they be termed "anaphylactoid purpura," a view which has been almost universally accepted The clinical reports of Osler,¹⁸ and more recently of Eyermann¹⁹ and others, have firmly established the importance of the allergic mechanism as an etiologic factor in a considerable portion of the cases of simple purpura without coagulation defect It is interesting to note that in 1914 Osler stated that 'perhaps the anaphylactic key will unlock the mysteries of the purpuras''

Thus by the middle of the nineteenth century the multiplicity of etiologic factors in purpura was well recognized It was known that it might occur as a result of or in association with a varied group of clinical states including infections, diseases of the blood, malignancies, cachexia, endocrine disturbances, deficiency states in addition to gastro-intestinal, skin and rheumatic syndromes that are now regarded as of allergic nature Clinical reports and experience since that time have confirmed amply the existence of all of these factors, and in recent years have emphasized the importance of the allergic group

Until the latter part of the nineteenth century, purpura was considered simply as a vascular disease because of the paucity of knowledge of blood coagulation defects There had been no knowledge of the existence of blood platelets until the studies of Donne²⁰ (1842) suggested the presence of a third cellular substance in the blood Hayem²¹ confirmed these studies in 1878 and Bizzozero²² completely established the identity of blood platelets in 1882 Brohm²³ (1881), Denys²⁴ (1887) and Hayem²⁵ (1895) soon discovered the fact that the blood platelets were sharply reduced in some cases of purpura though not in all

In the decade or two which followed the discovery of the relation of platelet reduction to purpura, profound changes occurred in the interpretation of the disease Attention was focused primarily on the platelet reduction, and clinical cases were divided into thrombocytopenic and nonthrombocytopenic types with subdivision into secondary and primary groups depending upon whether or not they were associated with recognizable clinical disease Partly because of its dramatic clinical manifestations, and partly because of the absence of tangible etiologic clues, primary thrombocytopenic purpura quickly occupied the center of attention and has retained that position to the present time Numerous synonyms have developed, including essential and idiopathic thrombocytopenic purpura and Morbus maculosis Werlhofii, with varying appropriateness It is important to recall also that, prior to the time when the concept of primary thrombocytopenic purpura came into existence, it was impossible to differentiate severe purpura from hemophilia, hypoprothrombinemia and fibrinogenopenia as we know them today Consequently it is not surprising that thrombocytopenic purpura, with its severe and often lethal blood loss, should have been grouped with these diseases under the general title of hemorrhagic diseases and more or less separated from its closer allies, the nonthrombocytopenic or simple purpuras This confusion was rela-

tively short-lived however and was cleared by the development of practical methods for the enumeration of platelets, demonstration of the lack of syneresis in thrombocytopenic purpura (Hayem),²⁵ development of satisfactory methods for determination of coagulation time, development of the tests for bleeding time (Duke)²⁶ and prothrombin time (Quick),²⁷ and the clinical observations of Hayem,²⁵ Minot,²⁸ Duke,²⁹ and many others

The pathogenesis of the thrombocytopenia which was found in the last decade of the nineteenth century to occur so frequently in association with purpura has been the subject of many experimental and clinical studies since that time, although a few workers have maintained interest in the vascular phases of the disease, and a still smaller number have steadfastly persisted in efforts to correlate the vascular and hematologic phases. Hayem suggested that the reduction of platelets was due to decreased production or increased destruction of those elements, but since the origin and fate of the platelets were still unknown at that time he was unable to throw any light on either mechanism. Significantly, however, he did suggest the possibility of an allergic factor in the latter mechanism by demonstrating the reduction of platelets in 'anaphylactic' states after peptone injection, and with heterologous serum. He also demonstrated platelet reduction in severe infections. It was during this period, apparently, that the concept of the vascular changes being due to the platelet reduction gained favor, a concept which contributed much to the confusion of the subsequent years. Hayem's experimental work with heterologous serum doubtless provided the background for the tremendous interest in the reduction of platelets by the use of antiplatelet sera which was studied by many observers during the early part of the twentieth century and which demonstrated beyond question the susceptibility of the platelets to antiplatelet substances of biologic origin.

It was also during this period that the origin of the platelets in the megakaryocytes of the bone marrow was established by Wright³⁰ and corroborated by Bunting³¹ and by Downey.³² This observation provided a valuable clue to the mechanism by which platelet reduction might occur as a result of decreased production, and it was soon established by Duke,²⁹ Minot,²⁸ and others that platelet deficiency did occur in bone marrow diseases such as leukemia and aplastic anemia. Duke also confirmed the reduction of platelets in severe infections, notably diphtheria and tuberculosis, after peptone injection, after massive x-ray irradiation (Heineke),³³ demonstrated reduction by chemical toxins of the benzol type and, most importantly from the allergic standpoint, showed experimentally the reduction of platelets as a result of a hypersensitivity mechanism in rabbits sensitized to horse serum. Except for our present incomplete knowledge of deficiency of maturation factors and the role of the spleen, the etiologic background of thrombocytopenia was as complete in theory at that time as it is today. Myelopathy, severe infection and toxemia, chemical intoxication, x-ray irradiation, and allergic reaction had been established as important mechanisms capable of causing a reduction of platelets in the peripheral blood.

It was at that point that the tremendously important role of the spleen in platelet reduction was discovered more or less by chance. Kaznelson³⁴ demonstrated, and

many others have amply confirmed, prompt and dramatic increase of the circulating platelets following splenectomy in certain cases of thrombocytopenia. Interestingly, Elliott³⁵ has also demonstrated prompt reversal of the vascular changes following splenectomy in cases of purpura with thrombocytopenia. In the intervening thirty years splenectomy has been established as the standard therapeutic approach to cases of "primary" or "idiopathic" thrombocytopenic purpura, and has been shown to be particularly effective in those instances in which there is an ample number of megakaryocytes in the bone marrow. In spite of that position in therapy, however, removal of the spleen still remains a somewhat empiric procedure, for the mechanism by which it influences the level of the platelets in the circulating blood has never been clarified. There is still uncertainty and controversy as to whether the spleen destroys the platelets, inhibits their development in the bone marrow, or controls their release from the marrow, and what relation if any it bears to the allergic mechanism which seems to bear close resemblance to splenic action clinically.

Unfortunately, methods for the clinical study of the allergic mechanism in the production of thrombocytopenia, which has been so convincingly demonstrated experimentally, have been relatively unsatisfactory. However thrombocytopenia with purpura following ingestion of various drugs has been reported by Loewy,³⁶ Peshkin and Miller³⁷ and others, and thrombocytopenia has been produced at will in some of those patients by readministration of the offending drug and by skin testing, thus establishing the reaction as of allergic type. Further, demonstration of the allergic mechanism responsible for the granulopenia in agranulocytic angina,³⁸ and of the fact that sensitivity could be detected in those instances by granulopenic response following ingestion of the offending allergens, has suggested that platelets might behave in a similar manner and has corroborated the soundness of the "ingestion" method of demonstrating thrombocytopenic response to allergenic substances. Utilizing that method of testing in addition to the usual allergic diagnostic methods, it has been increasingly possible in recent years to establish allergic reactions as one of the causes of clinical thrombocytopenia with or without purpura. Squier and Madison³⁹ and others have shown that allergenic foods are capable of producing thrombocytopenia by demonstrating platelet reduction following ingestion of those foods, and have shown return of the platelet count to normal levels after the removal of the foods from the diet with clinical recovery.

Thus it is evident that in the evolution of knowledge of etiologic factors in thrombocytopenia and in purpura, allergy has been established as one of several factors capable of producing thrombocytopenia and likewise as one of several similar factors that are capable of producing the vascular changes characteristic of purpura. The curious similarity of these etiologic factors may well explain why purpura occurs so much more frequently in association with thrombocytopenia than with hypoprothrombinemia or thromboplastin deficiency. In the case of the allergic factor it is readily conceivable that an allergic individual might have both hematologic and vascular response simultaneously and to the same allergen, producing typical thrombocytopenic purpura. Clinical evidence to support this possibility is accumulating slowly, and is derived principally from satisfactory

clinical response of both thrombocytopenia and purpura to allergic control without splenectomy. With advances in the technic of allergic studies, and with wider use of the ingestion method of testing, it is likely that more cases will be found to fall into the allergic category and to respond favorably to that method of therapeutic approach.

SUMMARY

It has been suggested that, for purposes of etiologic investigation, thrombocytopenic purpura be separated into its two component parts, thrombocytopenia and purpura, and that they be regarded as two coexisting abnormalities rather than as a single disease. Historical review of the development of knowledge of the pathogenesis of purpura emphasizes the importance and soundness of this dual approach. Both thrombocytopenia and purpura have been shown to have a complex etiologic pattern with multiple potential etiologic factors. The curious similarity of these two groups of factors may at least partially explain the frequent coexistence of the two abnormalities in the clinical picture of thrombocytopenic purpura.

It has been shown that allergy has long been recognized as an etiologic factor of major importance in both purpura and thrombocytopenia. It is logical, therefore, that it should frequently be an important etiologic factor when the two conditions exist together, and it is suggested that when diagnostic methods are more adequate a considerable number of cases of "idiopathic" thrombocytopenic purpura will fall into that category and will yield therapeutically to a proper allergic approach.

A STUDY OF THE BONE MARROW FROM THIRTY-SIX PATIENTS WITH IDIOPATHIC HEMORRHAGIC (THROMBOPENIC) PURPURA

By L. W. DIGGS, M.D., AND J. S. HEWLETT, M.D.

IN RECENT summary articles by Nickerson and Sunderland,¹ Rosenthal,² Tocantins,³ Wiseman, Doan and Wilson,⁴ Limarzi and Schleicher,⁵ and Dameshek and Miller,⁶ the extensive literature dealing with idiopathic hemorrhagic purpura is reviewed, and the known facts relating to the megakaryocytes and to the bone marrow are presented.

The majority of observations have been made on autopsy material, and there have been relatively few quantitative studies of material aspirated from the marrow.⁵⁻⁶ General statements are often made concerning the value of the bone marrow examination in thrombopenic conditions, but specific facts are few. Because of the paucity of quantitative information, a lack of correlation of the marrow findings with prognosis, and differences of opinion concerning the number and morphology of megakaryocytes, a further study of the bone marrow seems justified.

In this paper the observations made at the Cleveland Clinic on the bone marrow smears of 36 patients with idiopathic hemorrhagic purpura, and the correlation of the findings with the clinical picture, are presented.

All of the patients had in common purpura, spontaneous bleeding from mucous surfaces, platelet counts below 100,000 per cu. mm., prolonged bleeding time, defective clot retraction, and normal or only slightly prolonged coagulation time. Smears from patients with demonstrable primary disease, leukemia, aplastic anemia, malignancy, nephritis, cirrhosis, or infections, or who gave a history of allergy or of taking drugs previous to hemorrhagic episodes, were excluded. Splenectomies, performed on 22 of the 36 patients, revealed normal or only slightly enlarged spleens. The tissue changes in the spleen were consistent with the diagnosis of essential thrombopenic purpura as defined by Nickerson and Sunderland. Unless specifically stated, all observations were made on marrow aspirated during the acute hemorrhagic phase of the disease.*

The marrow was obtained by needle puncture of the body of the sternum in the midline at the level of the third rib. A minimal amount of marrow was aspirated, usually less than 0.2 cc. Smears were made directly from the point of the needle using the coverslip technic. The smears were stained with Wright's stain. Smears which contained relatively few nucleated red cells or early myeloid cells, and which were obviously diluted with peripheral blood, were not included in this study.

THE BONE MARROW—GENERAL

The principal value of the bone marrow examination in thrombopenic purpura is to differentiate idiopathic hemorrhagic purpura from aplastic anemia, leukemia,

From the Department of Clinical Pathology, Cleveland Clinic Foundation, Cleveland, Ohio.
* Appreciation is expressed to Dr. Russell L. Haden, who performed the majority of sternal aspirations, preserved the smears for study, and who has allowed us to use the marrow and clinical material for this presentation.

and other conditions. In making this differentiation the megakaryocyte plays a part, but the other cells play a major role.

The bone marrow in idiopathic hemorrhagic purpura is cellular and there is little fat. The erythroid-myeloid ratio is normal in the majority of instances, but there is a tendency toward a relative increase in the nucleated red cells which sometimes approaches a 1:1 ratio. The distribution of nucleated cells in the bone marrow

FIG. 1. Frequency distribution of nucleated cells in marrow smears of 10 patients with idiopathic hemorrhagic purpura. The range of cells in nonhemorrhagic control cases is represented by the shaded areas.

smears of 10 of the patients of our series which is representative of the group as a whole is given in figure 1.

There is a slight left shift in the maturity of the myeloid cells with the majority of cells at the metamyelocyte to filament stage. The eosinophils and lymphocytes are usually normal, but may be increased. Each of the following cell types, undifferentiated primitive cells, histiocytes, mononuclears, plasma cells, and megakaryocytes, constitute less than 1 per cent of the nucleated cells. The nucleated red cells are mostly at the late erythroblast-normoblast level of maturation and appear normal in size, shape, and hemoglobin content. In patients with chronic purpura who are anemic as the result of blood loss, the nucleated erythrocytes

may be smaller than normal, their cytoplasm more basophilic, and their shape irregular. Platelets are difficult to find. Cells with vacuoles, toxic granules, and pyknotic nuclei or other signs of degeneration, are infrequent.

In aplastic anemia the marrow is relatively acellular. There is an absolute and relative decrease in myeloid and erythroid elements and a relative increase in lymphocytes, mononuclear cells, plasma cells and histiocytes. The lymphocytes and mononuclears are of a mature variety. There are few primitive cells. Megakaryocytes are difficult to find. The red cells reveal abnormalities in size and shape, and there are often atypical and degenerated leukocytes.

In smears from patients with leukemia there are numerous cells, usually of one variety. The normal marrow cells tend to be replaced. As a rule there are numerous primitive cells or "blasts." The megakaryocytes in leukemias at a stage in which there is purpura and thrombopenia are usually significantly decreased.

In our experience, the bone marrow examination has been of limited value in differentiating primary thrombopenic purpura from thrombopenia secondary to nephritis, Hodgkin's disease, disseminated lupus or malignancy. We have not had opportunity to observe a sufficient number of cases of purpura secondary to chemical poisoning or infections to draw conclusions, but degenerative changes in megakaryocytes and in other cells have been described in these conditions.⁷

NUMBER OF MEGAKARYOCYTES

The number of megakaryocytes in relation to other nucleated cells in smears of the bone marrow from normal individuals and from patients with idiopathic thrombocytopenic purpura as reported in the literature are summarized in table 1.

In our series, the megakaryocyte counts of bone marrow from 36 patients with idiopathic hemorrhagic purpura were made by noting the number encountered while counting 10,000 consecutive nucleated cells. All of the counts were made under high dry magnification or oil immersion. A tally counter was employed to facilitate counting. The number of megakaryocytes ranged from 3 to 59 per 10,000 nucleated cells, with an average of 17 (table 1).

Two sternal punctures performed on each of two patients within a period of three weeks, during which time there were active hemorrhagic phenomena, revealed megakaryocyte counts of 4 and 12 in one case, and 8 and 4 in the other.

In 50 bone marrow smears from patients with miscellaneous nonhemorrhagic conditions who had no evidence of blood dyscrasias and who had essentially normal marrows, the megakaryocytes ranged from 1 to 54, with an average of 16 per 10,000 nucleated cells. In this series the megakaryocytes were counted in consecutive fields, but the nucleated cells were counted in every tenth field until 1000 cells had been noted. The frequency distribution of the megakaryocytes in idiopathic hemorrhagic purpura and in nonhemorrhagic conditions is given in figure 2.

The number of megakaryocytes per low power field was estimated in 24 coverslip marrow preparations from patients with idiopathic hemorrhagic purpura. Twenty-five consecutive low power fields were examined in each case. It was found that the number per low power field varies from 0.0 to 8.2, with an average of 1.1.

TABLE 1—*The Range and Average Number of Megakaryocytes per 10,000 Nucleated Marrow Cells*

FIG. 2. Frequency distribution of megakaryocytes per 10,000 nucleated cells in bone marrow smears from 36 patients with idiopathic hemorrhagic purpura and 50 patients with miscellaneous nonhemorrhagic conditions.

Dameshek and Miller state that the average megakaryocyte count for miscellaneous conditions is just over 1, with a range from 0 to 5.

Our observations agree with those found by previous observers that the number of megakaryocytes in idiopathic thrombopenic purpura is within the normal range, and that in some cases it is increased beyond the normal average. In several cases, not included in this series, in which the bone marrow smear was not considered satisfactory because of dilution with peripheral blood, the megakaryocytes were less than 1 per 10,000 nucleated cells, but in all preparations considered adequate for study megakaryocytes were readily demonstrable.

THE RELATION OF THE MEGAKARYOCYTE COUNT TO PROGNOSIS

In order to test the truth of the common belief that patients with high megakaryocyte counts have a good prognosis and will respond favorably to splenectomy, whereas those with low counts have a poor prognosis, we arranged our patients according to the number of megakaryocytes per 10,000 nucleated cells and tabulated deaths, recurrences, and cures (tables 2 and 3). It is noted that there is no correlation between the number of megakaryocytes found in the marrow smears during the acute phase of the disease and the prognosis with or without splenectomy.

In patients with idiopathic thrombopenic purpura whose spleens were removed,

it was noted that there was a marked variation in the platelet response in different patients after operation (fig 3)

Of 22 patients subjected to splenectomy, 3 failed to show a platelet rise above 100,000, and 4 sustained a rise of from 100,000 to 200,000 platelets over a three-

FIG 3 Platelet response following splenectomy in patients with idiopathic hemorrhagic purpura week postoperative period. Six patients responded with a platelet rise of 200,000 to 500,000, and 7 patients with a rise to 500,000 or more over the same postoperative period. There was no apparent correlation between the number of megakaryocytes and the platelet count following operation. One patient died soon after the spleen was removed. One patient was operated upon at another hospital.

THE MORPHOLOGY OF MEGAKARYOCYTES

The megakaryocytes were classified as megakaryoblasts, immature, intermediate,

or mature megakaryocytes, or as naked nuclei. The criteria used for the identification of each group are as follows:

1. *Megakaryoblast* (fig. 4 A, B). This cell has a diameter of 15 to 30 microns

FIG. 4 A Undifferentiated stem cell (?) Megakaryoblast B Megakaryoblast in mitosis Nongranular cytoplasm Blunt cytoplasmic projections C Very immature megakaryocyte with two nuclei Minimal amount of finely granular cytoplasm near the nucleus Blunt nongranular pseudopods D Immature megakaryocyte Finely granular cytoplasm Multiple nongranular cytoplasmic tags

The shape is usually irregular and there are multiple blunt cytoplasmic projections. The nucleus is single, relatively large, round or slightly indented, and has a fine, lace-like chromatin structure which takes a predominantly acidophilic stain. Nucleoli may or may not be present. The cytoplasm is relatively small in amount, is nongranular, takes a basophilic stain and may have a spongy appearance.

2. *Immature megakaryocyte* (synonym promegakaryocyte, early megakaryocyte)

Fig 4 C, D, fig 5 E, F, G) This cell is larger than the megakaryoblast, being 20 to 50 microns in diameter. The shape is irregular, and there are varying numbers of cytoplasmic tags and rounded pseudopods. The nucleus is indented or divided

FIG 5 E Immature megakaryocyte with perinuclear granular cytoplasm. Spongy, nongranular peripheral cytoplasm and pseudopods. F Immature megakaryocyte with multilobulated nucleus. Granular area next to nucleus. Peripheral spongiosplasm. G Immature megakaryocyte with granules next to nucleus, surrounded by a coarsely vacuolated zone and peripheral fine, spongy cytoplasm. H Intermediate megakaryocyte with ill-defined margins. Multilobulated, pyknotic nucleus. Granular cytoplasm. Absence of spongy layer at periphery.

into two or more lobes and has a moderately coarse chromatin structure without nucleoli. The cytoplasm stains blue and is likely to be darker near the nucleus than at the periphery. Fine bluish granules are demonstrable next to the nucleus, but granules are absent in the peripheral portions and in the pseudopods. The pseudopods often contain multiple small vacuoles.

3 *Intermediate megakaryocyte* (fig 5 H, 6 I, J) This cell is quite large, often measuring 50 to 80 microns in diameter. Its shape is usually round and the margins relatively smooth, but the edge may be frayed or there may be cytoplasmic tags

Fig 6 I Intermediate megakaryocyte Large cell Relatively smooth margin Hyperlobulated, pyknotic nucleus Fairly evenly distributed coarse granules No platelet differentiation J Intermediate megakaryocyte K Mature megakaryocyte Granular platelet differentiation L Naked, multilobulated, pyknotic nucleus

The nucleus is relatively small, is multilobular, and has a coarse chromatin structure. The cytoplasm varies in shade from blue to pink and is diffusely granular. The granules are relatively coarse. There may be vacuoles in the cytoplasm and a tendency toward a clumping of the granules, but there is no differentiation of well-defined granular platelets.

4 *Mature megakaryocyte* (fig 6 K) The mature megakaryocyte resembles the inter-

mediate cell in nuclear, cytoplasmic, and granular structures, but differs from it in that granular platelets are demonstrable. The platelets usually form small masses at the periphery, but the whole cytoplasm may be composed of granular platelet masses. The size of the cell varies widely from huge forms that practically fill the oil immersion field to fragments of nuclei with only a few platelets attached to them.

5 *Naked nucleus* (Fig. 6 L). In this form there is a pyknotic, lobulated nucleus and no cytoplasm.

There is often asynchronism in the maturation of nucleus and cytoplasm of megakaryocytes. Thus, one may have a multilobulated nucleus in a cell with basophilic nongranular cytoplasm or a single round immature nucleus in a relatively small cell which is actively producing granular platelets. Any cell which is producing granular platelets is called mature. The hyaline cytoplasmic projections and filaments and the spongy pseudopods are not considered as true platelets, but as artefacts, due to the tearing of the cell away from its fixed tissue connections or as evidence of amoeboid activity. Similar platelet-like structures are found in reticulum cells, malignant cells, plasma cells and in the early myeloid, erythroid, and lymphocytic cells.

It is to be noted that the principal criteria for the differentiation of megakaryocytes are the granules⁵⁻⁸ and the presence or absence of granular platelets. The megakaryoblasts have no granules, the immature cells a few fine granules unevenly distributed, the intermediate cell has coarse granules fairly evenly distributed, but no well-defined platelets, and the mature cell has coarse granules and platelet formation.

One variant of the immature megakaryocyte (fig. 5 G) is a cell with a perinuclear granular cytoplasm, surrounded by a symmetrical ring of coarsely vacuolated cytoplasm and at the extreme periphery cytoplasmic attachments that have a nongranular hyaline or finely spongy character. This cell has been interpreted by others to be a degenerate form, but we consider it to be a form transitional between the immature and intermediate form. The well-defined spongioplasm probably represents an area of cytolysis which leads to a shedding of the peripheral cytoplasm and attachments to other cells, and to the production of a free granular cell which from that stage on produces true platelets.

THE DIFFERENTIAL MEGAKARYOCYTE COUNT

The differential megakaryocyte counts in our series were made by examining 25 or more megakaryocytes. For the control series, 50 smears of bone marrow from patients with nonhemorrhagic conditions who had no evidence of blood dyscrasias were examined. The distribution of the various stages of the megakaryocyte is given in figure 7.

In the control series the mature megakaryocytes which are actively producing platelets are the predominant cells, whereas in idiopathic thrombopenic purpura the intermediate cell without platelet production is predominant. In idiopathic thrombopenic purpura there is also a relative increase in immature forms and in naked nuclei.

The finding of reduced platelet formation and immaturity of cells is in agreement with the findings of numerous workers and confirms the original concept of Frank⁹ and of Minor¹⁰ that there is dysfunction of the megakaryocytes which prevents normal platelet formation

FIG 7 Frequency distribution of megakaryoblasts, immature intermediate and mature megakaryocytes, and naked nuclei in sternal bone marrow smears of 22 patients with idiopathic hemorrhagic purpura in the acute stage on whom splenectomy was performed. The rate of variation in nonhemorrhagic conditions is represented by the shaded area.

THE EFFECT OF SPLENECTOMY ON THE MEGAKARYOCYTES

Sternal marrow aspirations were performed on two of our patients before and after splenectomy (table 4). In both instances there was a decrease in the relative number of megakaryocytes after splenectomy and an increase in the mature platelet-producing cells. Similar decreases in the number of megakaryocytes have been noted by Wiseman, Doan, and Wilson, and by Limarzi and Schleicher. Limarzi and Schleicher, Dameshek and Miller, and others have also observed that following splenectomy there is a decrease in early forms and an increase in adult forms.

In one of our patients the marrow examination after splenectomy during a recurrence of the purpura revealed a megakaryocyte number and differential which was essentially the same as before splenectomy.

PROGNOSIS BASED UPON THE NUMBER OF EOSINOPHILS IN THE MARROW

Schwartz¹¹ in 1945 reported that in thrombopenic purpura "increased numbers of eosinophils in the marrow signify a favorable response for spontaneous recovery, while scant numbers foretell a chronic course and necessity for splenectomy." He made direct smears of material aspirated from the sternum. The number of eosinophils per 1000 granulocytes at the metamyelocyte stage or older were counted.

Schwartz interprets an increase in the eosinophils of the marrow as a manifestation of an allergic state or evidence of sensitivity to infections, drugs, or allergenic foods. He states that those with more than 50 eosinophils per 1000 granulocytes have an acute onset, a relatively benign course, and spontaneous and complete clinical and hematologic recovery and that removal of the spleen in such "allergic" thrombopenias is not necessary.

The relation of the eosinophils to prognosis was studied in our series, using the same method of counting eosinophils as recommended by Schwartz. No correlation was found between the eosinophil counts and the deaths, recurrences, or cures with or without splenectomy (table 5). We do not accept the thesis that eosinophil increase in the bone marrow is always indicative of sensitivity to exogenous food, drug, or other factors. There is evidence that the eosinophilia may be a reaction which is secondary to the hemorrhage into the skin or other tissues.¹²

DISCUSSION

The variation in the number of megakaryocytes in different individuals with idiopathic thrombopenic purpura is in part due to true differences in individuals and in the distribution of bone marrow giant cells as has been shown in biopsy material by Lawrence and Knutti¹³ and in autopsy material by others, but much of the variation is due to dilution of the marrow cells with peripheral blood and other technical factors. Megakaryocytes and particularly early forms are partially fixed cells which are not readily aspirated. These cells are fragile and easily destroyed by any manipulative procedure. They contain large amounts of thromboplastin and tend to get caught in fibrin webs which rapidly form around them. They are large cells which are pushed toward the margins and ends of slide preparations. We have found that the megakaryocytes in the best of coverslip preparations were unevenly distributed and that counts made on the same smears by the same or different individuals varies as much as 100 per cent.

Since there are unavoidable errors involved in megakaryocyte counting, a wide range of variation in different individuals, and within the range of observed values, no correlation between the megakaryocyte counts and prognosis, it is obvious that there is little use in undertaking the laborious task of making actual counts.

Prognosis and indications for splenectomy are determined, not from the megakaryocyte study alone, but from the study of the entire patient. If the diagnosis is aplastic anemia, leukemia or secondary thrombopenia, splenectomy is not indicated.

If, in 2 drops of material aspirated from the marrow (4 coverslip or two slide preparations), there are twenty or more megakaryocytes, if the majority of the bone marrow giant cells are immature or intermediate and not actively producing

platelets, and if the rest of the marrow, peripheral blood and clinical picture fits, the diagnosis of idiopathic thrombocytopenic purpura is made and splenectomy may be recommended

The finding of numerous megakaryocytes which are actively producing granular platelets is against the diagnosis of essential thrombopenic purpura or is indicative of a spontaneous remission in a known case. Splenectomy in such cases is contraindicated

The peculiar distribution of megakaryocyte types in some patients with essential thrombopenic purpura (fig 7) in which there are few mature forms, yet an increased number of naked nuclei, suggests that the intermediate cells disintegrate without going through the platelet producing stage. This is additional evidence that the low platelet count found in this disease is due to defective formation of platelets rather than to excessive destruction outside of the bone marrow

SUMMARY AND CONCLUSIONS

1 Observations made on the bone marrow smears of 36 patients with idiopathic hemorrhagic purpura and the correlation of the findings with the clinical picture are presented. The control series consisted of 50 patients with nonhemorrhagic conditions without blood dyscrasias

2 The bone marrow in idiopathic hemorrhagic purpura is hyperplastic. There is a slight myeloid and erythroid immaturity and in some cases a slight eosinophilia and lymphocytosis

3 The megakaryocyte counts ranged from 3 to 59 per 10,000 nucleated cells, with an average of 17. In the control series the megakaryocytes ranged from 1 to 54 per 10,000 nucleated cells, with an average of 16

4 There appears to be no correlation between the number of megakaryocytes found in the marrow smears during the acute phase of the disease and the prognosis with or without splenectomy. There is also no apparent correlation between the number of megakaryocytes and the platelet response following splenectomy

5 The megakaryocytes were classified as megakaryoblasts, immature, intermediate, or mature megakaryocytes, or as naked nuclei. The principal criteria for the differentiation of megakaryocytes are the granules and the presence or absence of granular platelets

6 The differential megakaryocyte counts were made by examining 25 or more megakaryocytes. In the control series the mature megakaryocytes which are actively producing platelets are the predominant cells, whereas in idiopathic hemorrhagic purpura the intermediate cell without platelet production is predominant

7 Marrow studies on 2 of our patients before and after splenectomy revealed a decrease in the relative number of megakaryocytes and an increase in the number of platelet-producing cells following operation

8 No correlation was found between the eosinophil counts and the deaths, recurrences, or cures with or without splenectomy

9 The principal value of the bone marrow examination in cases of suspected idiopathic hemorrhagic purpura is to exclude leukemia and aplastic anemia

THROMBOCYTOPENIC PURPURA COMPLICATING GOLD THERAPY FOR RHEUMATOID ARTHRITIS

REPORT OF THREE CASES WITH SPONTANEOUS RECOVERY AND ONE CASE WITH
RECOVERY FOLLOWING SPLENECTOMY

By STACY R. METTIER, M D, ALICE McBRIDE, A B, AND
JONAH LI, M D

IT IS A WELL established fact that certain drugs may cause thrombocytopenic purpura. With the introduction of the ever-increasing number of new drugs in the treatment of disease, this untoward reaction becomes more and more a medical problem. Mild to severe hemorrhagic tendency has been reported as occurring during the course of administration of sedormid, the sulfonamids, the arsphenamines, sodium salicylate, and other drugs. Recently an increasing number of occurrences of thrombocytopenia have been reported as resulting from the injection of gold salts for rheumatoid arthritis.

Hartfall, Garland, and Goldie¹ treated 900 patients with arthritis with injections of gold salts, and among this group there were 11 cases of purpura hemorrhagica. Three of these progressed to a fatal termination. There was no correlation between the severity of the platelet reduction and recovery or fatal termination.

Of the 245 patients treated with gold salts by Cecil, Kammerer, and De Drume,² 3 showed purpuric lesions in the skin. The lesions subsided when the drug was discontinued.

Price and Leichtenstritt³ reported a series of 100 patients who had received gold salts, and 3 developed thrombocytopenia. Two of the patients recovered after withdrawal of the drug but the third died.

Short, Beckman and Bauer⁴ treated a group of 47 patients with rheumatoid arthritis with injections of myochrysine in doses of 100 milligrams of the drug. One of their patients developed a severe hemorrhagic tendency with bleeding from the gums and nose. Platelets were not found present in the blood smear. In spite of repeated transfusions, the patient continued to show widespread bleeding, and death occurred five weeks after the onset of the purpura.

During the past seven years in the wards and out-patient department of the University of California Hospital, 160 patients, on whom a diagnosis of rheumatoid arthritis had been made, were given gold salt therapy. During the course of treatment 4 of the patients developed thrombocytopenia and purpuric manifestations. The results of the observations made on these 4 patients are reported.

CASE 1

A W. A white American female, 44, was examined May 28, 1943. She stated that three years earlier she had first noticed a painful swelling of the middle joint of the third finger of the right hand. Since that time swelling accompanied by pain had appeared in other joints of the fingers and spread to involve the

From the Division of Medicine, University of California Medical School, San Francisco.
Supported by a grant from the Cecilia Benfield Fund and the James Foundation.

wrists, shoulders, elbows and ankles. In recent months she had lost considerable weight but was unable to estimate the amount.

Physical examination The patient appeared of small stature and structure. A survey of the skeletal system revealed a moderate degree of swelling of the interphalangeal joints of both hands. There was a soft fluctuant swelling over the dorsum of the right wrist. Both ankles were swollen and markedly tender to the pressure of the fingers.

Laboratory data Examination of the blood showed hemoglobin, 64 per cent (11 grams with standard at 17.2 grams per 100 cc), erythrocytes, 3,780,000 per cubic millimeter, leukocytes, 8800 per cubic millimeter, and platelets, 300,000 per cubic millimeter. Sedimentation of the erythrocytes was 37 millimeters in one hour. The plasma content of ascorbic acid was 1.7 milligrams per 100 cc and the uric acid was 3.3 milligrams per 100 cc.

Diagnosis Rheumatoid arthritis, hypochromic anemia.

Course of the illness The patient was returned to her physician for treatment with the advice that she receive injections of myochrysine in doses of 50 milligrams intramuscularly at intervals of one week. She was examined again December 15, 1943, at which time there had been a gain in weight of 6 pounds. She considered herself to be in good health and there was no apparent swelling of the joints previously involved. The hemoglobin was 116 per cent (Sahli) and the rate of sedimentation of the erythrocytes was 22 millimeters in one hour. The gold therapy was discontinued.

Three months later, March 11, 1944, the patient was admitted to the hospital because of recurrence of swelling of the joints and a moderate hypochromic anemia. Daily physical therapy consisting of radiant heat, massage, and passive exercise to the involved joints was given the patient. One month later, April 17, the patient received an injection of myochrysine, 25 milligrams in the buttocks. The following day a fine purpuric rash appeared and was widely spread over the body. Soon after there was moderate epistaxis on two occasions.

Examination of the blood showed erythrocytes, 3,050,000 per cubic millimeter, hemoglobin, 59 per cent (8.5 grams) Sahli. The white blood cells were 6650 per cubic millimeter. It was of interest that 3 per cent of the total leukocyte count was of the eosinophile variety. The blood platelets were 90,000 per cubic millimeter and there was a markedly increased fragility of the blood capillaries.

The patient was given a whole blood transfusion of 500 cubic centimeters. One week after its appearance the purpura had completely disappeared and the platelets had returned to normal numbers.

CASE 2.

J. W. A white American man, 50, reported to the outpatient department of the University of California Hospital March 8, 1946, complaining of pain in the shoulders, elbows, wrists, hands, knees, and feet extending back over a period of ten years. Although he had carried on his usual occupation as a clerk, he had found it more and more difficult to get about because of progressive disability of the lower extremities and limited motion of the elbows and shoulders. Surgical removal of the thyroid gland had been accomplished at the age of 18 in an attempt to relieve hyperthyroidism complicated by exophthalmus.

Physical examination The arms were held rigidly to the patient's sides. With passive motion, practically no abduction of the right arm was possible, but elevation of the left arm to 20 degrees was accomplished with difficulty. There was mild, slightly painful swelling of the various interphalangeal joints, and there was thickening of the tissues on the dorsum of the wrists and about the knees and ankles. There was considerable atrophy of the muscles adjacent to the involved joints. An exophthalmus was still present as a residuum of the previously overactive and enlarged thyroid gland.

Laboratory data The blood count showed hemoglobin, 100 per cent (14.5 grams) Sahli, erythrocytes, 4,990,000 per cubic millimeter, and leukocytes 9960 per cubic millimeter. The platelets were reported to appear in an abundance on the stained films of blood. The blood uric acid was 3.5 milligrams per 100 cc. Sedimentation of the erythrocytes occurred at the rate of 33 millimeters in one hour. An estimation of the rate of basal metabolism was recorded at 18 per cent above normal. The plasma cholesterol was 300 milligrams per 100 cc.

Course of the illness On April 1, 1946, the patient was given his first injection of 50 milligrams of myochrysine (gold sodium thiomalate). The injections were repeated at intervals of one week accompanied by considerable improvement in the patient's well-being. On December 17, 1946, the patient received his

twenty fourth injection which on this date made a total of 1200 milligrams of the colloidal suspension (myochrysine)

The patient failed to report for further treatment until seven weeks later, February 4, 1947, when gold therapy was resumed. He received the usual injection of 50 milligrams of myochrysine. The patient returned on February 10, stating that two days before minute areas of hemorrhage had suddenly appeared in the skin of the lower extremities and forearms followed some hours later by hemorrhagic blebs in the mucous membranes of the lips. That evening he passed a very loose stool that contained a considerable amount of bright red blood. The patient also observed oozing of blood from the gingival border of the gums.

Laboratory data Examination of the blood on February 10 showed hemoglobin, 90 per cent, erythrocytes, 4,000,000 per cubic millimeter, and the leukocytes 7500 per cubic millimeter. The blood platelets were estimated at 80,000 per cubic millimeter. A specimen of blood clotted at the end of eight minutes but failed to show retraction after several hours. The prothrombin content of the blood was 90 per cent of normal. Sternal puncture showed an essentially normal marrow picture with single cells and scattered islands of nucleated red cells and granulocytes. The megakaryocytes were increased in number but showed a greatly diminished platelet production.

Further injections of colloidal gold were discontinued and the patient was requested to report at frequent intervals for observation of the hemorrhagic tendency. On examination February 13, the hemorrhagic lesions had faded considerably. The platelets were 145,000 per cubic millimeter. The patient reported again February 17, when all evidence of hemorrhage had subsided and the platelets were 170,000 per cubic millimeter.

CASE 3

S G A white American female, 33, was examined Nov. 5, 1946. Her illness started six years prior to entry, when she noted pain low in the back and the midthoracic region. Relief was obtained following the application of heat and the use of mild analgesics. Since then, there had been a recurrence of symptoms at intervals of one to two years. One year ago she became aware of pain in the cervical region and the gradual development of pain and swelling of the small joints of the hands. These symptoms have persisted since.

Physical examination The patient appeared slightly underweight and evidenced discomfort along the back. There was slight swelling of the first, second, and third metacarpophalangeal joints of both hands and of the proximal phalangeal joints of the middle fingers. Pain was elicited in those joints on pressure. There was stiffness of the cervical spine and forward flexion was limited to one-fourth the normal range. There was spasm of the paravertebral muscles in the lumbar region. Forward flexion of the lumbar spine was limited to three-fourths of the expected normal range. During this maneuver flattening of the spine became apparent in this region. No abnormalities were found on examination of the heart and lungs. Neither the spleen nor the liver could be felt.

Laboratory data The blood count showed hemoglobin, 69 per cent (11.9 grams), erythrocytes, 3,820,000 per cubic millimeter, and leukocytes, 6800 per cu. mm. The platelets were 350,000 per cubic millimeter. The plasma ascorbic acid was 1.9 mg. per 100 cc. The rate of sedimentation of the erythrocytes was 26 millimeters per hour. On examination of the roentgen films, narrowing of the cervical-dorsal interspace was apparent and the margins were sclerotic. The regional apophyseal joints, especially the eleventh dorsal, showed marginal sclerosis.

Diagnosis Rheumatoid arthritis of the spine and of the metacarpophalangeal joints.

Course of the illness Over a period of seven days, the patient was given a course of roentgen irradiation to the spine consisting of a total of 675 R. Four weeks later a similar course of treatment was pursued. Soon after, this was followed by complete relief from the back pain.

On Nov. 14, 1946, one week after the patient had been last exposed to the roentgen rays, she was given, intramuscularly, an injection of myochrysine 0.025 grams (gold sodium thiomalate). Three weeks later when the patient reported for the expected third injection she stated that for the past two days a fine red nonpruritic rash had been visible over the lower extremities. There was no bleeding from the gums.

Laboratory data The blood count on Nov. 27 showed hemoglobin, 81 per cent (11.68 grams) Sahli, erythrocytes, 3,930,000 per cu. mm., and leukocytes, 3250 per cu. mm. The blood platelets were greatly

reduced and showed 65,000 per cu mm on actual count. A specimen of blood failed to show clot retraction. When the Dalldorf apparatus was reduced to a pressure of minus 20 millimeters of mercury and applied to the skin of the arm above the antecubital fossa, it induced the appearance of large numbers of petechial hemorrhages. This indicated increased fragility of the capillaries. A sternal puncture showed an essentially normal marrow with the exception of a slightly increased number of megakaryocytes. These failed to show evidence of platelet production.

Further injections of gold compound were discouraged. One week later on examination the petechial rash had almost entirely faded and there was no evidence of new lesions. When the platelets were enumerated, there were 160,000 per cu mm and four weeks later, 200,000 per cu mm.

COMMENT

The three case histories reported above are examples of thrombocytopenia arising secondary to intramuscular injections of a colloidal suspension of gold (myochry-sine). This was accompanied by mild purpuric manifestations in two of the patients and was limited to petechial hemorrhages in the skin. In the third patient the hemorrhages were not only more extensively distributed over the body but were accompanied by bleeding from the nose and gastrointestinal tract. After three or four days without specific therapy, the blood platelets appeared spontaneously in the circulating blood in all of the patients in increasing numbers, coincident with the disappearance of the hemorrhagic tendency. At no time did the lives of the patients appear to be in jeopardy.

CASE 4

R. B., a white American female, 44, was first examined Nov. 15, 1945. She stated that one year earlier she noted swelling of the small joints of both hands. Soon after, swelling, accompanied by pain, appeared in the wrists, elbows, knees, ankles, and small joints of the feet. During the past four months there had been a loss of 30 pounds in body weight.

Physical examination. On admission she appeared ill and underweight. Locomotion was accomplished with considerable pain and difficulty. There was marked pallor of the mucous membranes and of the palms of the hands. There was swelling of the middle interphalangeal joints of both hands, of the metacarpophalangeal joints, and at the wrists. There was slight ulnar deviation of the fingers. Extension of the forearms on the elbows was limited to 165 degrees. The shoulder joints were restricted to less than one half their normal range of motion. There was slight degree of swelling of the left knee and both ankles. A low pitched murmur was heard over the apex of the heart during systole and was thought to be of hemic origin. The spleen and liver could not be palpated.

Laboratory data. The blood count showed erythrocytes, 3,060,000 per cubic millimeter, hemoglobin, 38 per cent (6.5 grams) cenco, Sheard-Sanford electric photometer calibrated to 17.2 grams of hemoglobin per 100 cc blood, and leukocytes 7100 per cubic millimeter. The differential count was within normal range. The content of whole blood uric acid was 4.2 mg per 100 cc, and the plasma ascorbic acid was 0.45 mg per 100 cc. The hematocrit was 22.5 per 100 cc of blood. The sedimentation rate (corrected) was 10 mm per hour. The blood platelets were 220,000 per cu mm. The mean corpuscular volume was 70 cubic microns, the mean corpuscular hemoglobin concentration was 28 per cent, the mean corpuscular hemoglobin was 18 micrograms.

Clinical diagnosis. Rheumatoid arthritis, hypochromic anemia.

Course of the illness. On Nov. 20 and 23, the patient received transfusions of 500 cc each of whole blood which were followed by an increase in the hemoglobin to 60 per cent (10.3 grams) and in the red cell count to 3.74 M. Medication consisted of the oral administration of ascorbic acid 100 mg and ferrous sulphate 1.2 grams in divided doses daily. On Nov. 19, the patient received her first injection of colloidal gold (myochry-sine, gold sodium thiomalate) 0.025 grams or 0.0125 grams actual gold. At the end of the fourth week the patient complained of a generalized itching rash which was erythematous in character. The injections of colloidal gold were discontinued. Two weeks later, Dec. 31, the patient returned stating

that the rash had disappeared. She stated that she was having much less pain, was more active and her general feeling of well being had improved. There was an increase in weight from 105 pounds at the onset of illness to 111 pounds on this date.

On Jan 21, 1946, the date she should have received her ninth injection of colloidal gold, there suddenly appeared some oozing of blood about the lower right premolar and there were innumerable petechial hemorrhages on the lower extremities. The blood count showed erythrocytes, 4,810,000 per cu mm, hemoglobin, 73 per cent (10.5 grams) Sahli, leukocytes, 11,100 cells per cubic millimeter, and platelets, 215,000 per cubic millimeter. Following application of the sphygmomanometer cuff to the arm, and elevating the pressure to just above diastolic, there was the appearance of petechial hemorrhages in the antecubital fossa. Chryso therapy was discontinued until on examination, March 18, 1946, the hemorrhagic tendency had completely subsided. On this date the hemoglobin had increased to 84 per cent but there were no significant changes in the erythrocytes or platelets.

Injections of colloidal gold were started and repeated at intervals of one week until July 8, 1946, when petechial hemorrhages reappeared in the skin. On this occasion the blood platelets were found reduced to 100,000 per cubic mm. The patient reported at intervals of one week until Sept 16, when she stated that she had had a severe epistaxis and, for ten days, a constant menstrual flow. Examination of the blood showed erythrocytes, 3,670,000 per cu mm, hemoglobin, 55 per cent, platelets 110,000 per cu mm, and leukocytes 7450 per cu mm. There were 5 per cent eosinophiles.

During the month of September the patient suffered frequent attacks of epistaxis, and on the occurrence of the menstrual flow the period extended over fourteen days instead of the usual four days. On two successive days she was given whole blood transfusions of 500 cc. Roentgen irradiation of the ovaries was resorted to as an attempt to induce artificial menopause. The menses failed to appear on the expected date, but bleeding elsewhere had become more profuse. On Oct 23, there was continuous oozing of blood from the nose and the gingival margins. Large ecchymoses appeared in the skin and large numbers of red blood cells were observed in the urine. An enumeration of the platelets revealed 10,000 per cu mm of blood. The bleeding time was greatly prolonged. A specimen of blood showed a tendency to coagulate after a lapse of ten minutes but the clot was soft, friable, and failed to retract. A sternal puncture showed marked erythropoietic activity as evidenced by large islands of nucleated normoblasts and erythroblasts. There was moderate myeloid hyperplasia. There was a slight increase in the number of megakaryocytes. These seemed rounded, somewhat opaque, and showed no evidence of platelet production. For the past week the patient had been given four transfusions of whole blood without materially altering the bleeding. It was apparent that the patient's condition was becoming critical and was approaching the state of purpura fulminans. On Oct 24, splenectomy was performed by Dr. Leon Goldman. The spleen was found enlarged to about twice its normal size. With the exception of a mild febrile reaction following a transfusion, the patient's postoperative course was without untoward event. The abnormal bleeding stopped. Four hours after the operation was terminated, the blood platelets were 210,000 per cu mm, twenty-four hours later they were 325,000 per cu mm, and three months later were 550,000 per cu mm.

COMMENT

The fourth case history reported here differed essentially from the preceding three in the duration and severity of the hemorrhagic tendency. Two months after the first episode of thrombocytopenia a second series of injections of gold salt was started only to be interrupted at the end of four months because of a recurrence of bleeding. For the next three months the patient continued to exhibit spontaneous bleeding of varying degree. Finally with the occurrence of frank hemorrhage from the mucous membranes it was apparent that there was an acceleration in the bleeding disturbance. Splenectomy was performed following which there was a complete disappearance of the abnormal tendency to bleed.

DISCUSSION

The cause for the thrombocytopenia which may occur during the course of gold therapy is not well understood. It is possible that it may be an allergic phenomenon.

wherein the megakaryocytes become so altered as to interfere with the production of platelets. In the three patients on whom sternal puncture was performed, it was observed that the megakaryocytes, although slightly increased in number, appeared to be deficient in platelet production. This reaction, however, is not unique for the thrombocytopenia that occurs in gold therapy, since various investigators, including Frank⁵, Limarzi⁶, and Dameshek and Miller⁷ have described the apparent inactivity of the megakaryocytes in cases of so-called idiopathic thrombocytopenia.

In recent times the term "hypersplenism" has appeared in the medical literature. It is presumed that an abnormal spleen acts upon the bone marrow, or more specifically the megakaryocytes, to produce an inhibitory mechanism. Emphasis for this postulation is found in the greatly increased production of platelets soon after splenectomy.

The management of a patient with thrombocytopenia induced by gold salt therapy offers a serious problem to the clinician. In most instances the abnormal bleeding is of short duration. On the other hand, the bleeding may become enhanced and prolonged, may fail to respond to transfusions and ultimately lead to the patient's death. The question arises as to whether splenectomy should or should not be performed. It has been the consensus of opinion among surgeons⁸ that "splenectomy is not indicated but rather contraindicated in secondary thrombocytopenic purpura due to severe infections or intoxications." In none of the other reported cases of thrombocytopenia secondary to gold had splenectomy been attempted. In the present case the mild hemorrhagic disturbance of four months' duration became suddenly accelerated by the appearance of marked bleeding from the mucous membranes. It was felt that since the life of the patient was in danger, splenectomy was advisable. Soon after the operation there was a dramatic response of the platelets which led to the recovery of the patient.

Of interest in connection with the case reported here is the one reported by Farfel,⁹ wherein a patient with thrombocytopenia due to sulfathiazole therapy recovered following splenectomy.

SUMMARY

Of 160 patients treated with gold salt therapy, four developed thrombocytopenia with mild purpuric manifestations. In three patients there was a spontaneous remission and the hemorrhagic tendency disappeared in about one week's time.

In the fourth patient there was a second occurrence of thrombocytopenia which persisted over a period of four months, and finally failed to respond to transfusions. Splenectomy was followed by a dramatic rise in the blood platelets and recovery of the patient.

INCONSTANCY AND VARIABILITY OF THE VASCULAR FRAGILITY TEST EVEN IN PURPURIC CONDITIONS

By J. ROSKAM, M.D., CH. RENARD, M.D., AND L. SWALUE, M.D.

THE PATHOGENESIS of purpura is mysterious and complex. This is true for the origin of uncontrollable hemorrhages in Werlhof's disease and similar conditions. Clinical and experimental observations have indeed proved that the very long bleeding times occurring in hemogenic and hemophilo-hemogenic syndromes are due to the association of a hemic and a vascular factor (Roskam, ¹¹⁻¹²). Although the existence of the latter factor is established beyond doubt, its nature is not yet completely elucidated.

The breaking out of intradermal purpura seems also to result frequently from multiple factors (Grenet⁴, Bedson¹), seldom analyzed as yet.

Several authors have, however, emphasized the importance in the production of petechiae of the fragility of vessels of purpuric patients, as namely evidenced by the ease with which venous stasis produced a petechial eruption in these patients.

This induced purpura was described in 1911 by Frugoni and Guigni,² later by Weill (of Lyon) and Chancier¹⁶ in certain hemorrhagic conditions. The same year, Leede⁵ erroneously considered it as pathognomonic of scarlet fever. Later this phenomenon was systematically studied and was found by many authors in various conditions: intoxications, avitaminoses, diseases of the endocrine organs, of the spleen, the reticulo-endothelial system, of the sympathetic nervous system (Stephan¹⁶), in hypertension, solitary or combined with arteriosclerosis, in nephritis, in endocarditis lenta (Weissman¹⁷), in diabetes, in rheumatic patients given large amounts of sodium salicylate, in patients with gastro-duodenal ulcers treated with a milk diet and alkaline powders, in patients with chronic glaucoma (Roskam⁹), in erythremia, icterus, certain forms of tuberculosis (Schour¹⁴), etc.

The intensity of the purpura induced by venous stasis, "signe du lacet," capillary fragility test, capillary resistance test, or tourniquet test, etc., is approximated by the number of petechiae which appear during the test.

One of us has, however, repeatedly pointed out the "qualitative" and not "quantitative" aspect of the eruption, i.e., the importance of the size of the different purpuric elements. Petechiae with a diameter above one millimeter possess a significance similar to that of increased bleeding time (Roskam¹⁰).

These proportionally large petechiae are observed in subjects with a hemorrhagic condition. The more severe the condition, the larger is generally the diameter not of all petechiae, but of a certain number of them.

After this brief review, we will take the opportunity of describing two recent clinical observations to underline the diverse results in different circumstances of the "vascular" fragility test, as we prefer to call the "capillary" fragility test, for no one has proved that only capillaries are involved in that test.

From the Institute of Medical Clinic and Pathology, University of Liege, Belgium

CASE HISTORIES

Case 1 V Michel, male, 16, high school student

Family history irrelevant

Personal history measles, scarlet fever, diphtheria, appendectomy in childhood

Present disease At the beginning of December 1946, appearance of an eruption not disappearing by vitropression, made up of small elements grouped in clusters on the antero-medial aspect of the fore-arms and thighs. Later extension of this eruption mainly to the shoulders, to the anterior side of the legs, and to the ankles. Purple at their appearance, the small eruptive elements turn later brown-pink and yellow before disappearing. Several eruptive waves follow, always occurring in the skin areas involved in the first attack.

Physical examination On Jan 10, 1947, nothing unusual, except for pigmented sequelae of previous eruptions and for a few small submaxillary and axillary nodes.

Prothrombin time (Quick) 100 per cent

Bordet-Wasserman, Meinicke, Paul and Bunnel reactions negative

*Vascular fragility test** quantitative, ++++ qualitative, +++, only in the cutaneous areas corresponding to previous eruptions, as the petechiae induced by venous stasis are grouped in clusters and form eruptive blotches separated by areas of normal or almost normal skin (figs 1, 2, and 3)

One week later, despite the daily intake of 40 mg of citrin, similar vascular fragility test quantitative, ++++, qualitative, +++ in the cutaneous areas with sequelae of previous eruptions, almost negative between these areas

Case 2 Jacques, male, 17, high school student

Family history irrelevant

Personal history measles, chicken pox, mumps, whooping cough in childhood, appendectomy in 1941, frequent bronchitis, gastro-intestinal upset with fever in October 1946

FIG 2

Present disease On Saturday, January 25, 1947, the patient ate lobster with cocktail sauce, duck, and *pâte de foie gras*. Normal activity from January 26 to 28, but exposure to very cold weather during these three days. On Tuesday 28, purpuric stripes (length $1\frac{1}{2}$ -7 cm, width $\frac{1}{2}$ -2 $\frac{1}{2}$ cm) suddenly appeared on the face and neck. On the 29th, fever (about 38 C) which lasted for two days, headache and nausea, whereas the eruption faded out progressively and disappeared on Feb 10.

On Feb 2, at 8 P M, intake of two boiled eggs and again exposure to severe cold. At 9 P M, as his

* The vascular fragility test which we used is the test described by one of us in 1929 under the name of "signe due brassard" application above the elbow of the cuff (brassard) of Bouliette's oscillometer inflated half-way between the maximal and minimal arterial pressure of the patient. The pressure is held for 15 minutes. After decompression, there is examination of the induced purpura on the whole surface of the forearm and hand, and not, as later proposed by Wright and Lilienfeld,¹⁸ in a small area of the supero-medial aspect of the forearm.

FIG 3

FIG 4

father was weighing and measuring the patient, he saw the appearance of a new eruption which reached its maximum in a quarter of an hour. More numerous, the purpuric spots were localized on the face, neck, upper part of the chest, forearms, and wrists. Soon afterwards, fever (38.2 C), headache and nausea.

Physical examination On Feb. 3, 1947, in addition to the cutaneous eruption (figs. 4 and 5), there were slight fever (37.5-38.5 C) which disappeared progressively in ten days, a few petechiae on the soft palate, a few small nodes in the neck, groins and axillae, and a palpable spleen reaching the costal margin on percussion.

Sedimentation rate 4 mm in the first hour (Westergren)

Hemoglobin 100 per cent

Platelets 225,100 *Morphology* normal

Bleeding time Right ear 1', 1', 1 30", 2', 3' Left ear 3', 2', 1', 1', 2'

Clotting time 21', 23', 21', 23' (normal 16' to 24')

Prothrombin time (Quick) 100 per cent

Bordet-Wasserman, Meinicke, Widal, Wright's reactions negative

Paul and Bunnell's test + at 1/8

Hemoculture negative

Takata-Dohmoto's flocculation figure 59 (low, but still normal)

Weltman's coagulation band 0.4 (normal)

Vascular fragility test quantitative and qualitative practically negative on this day, as well as later, when the eruption was fading or had disappeared

As the history and tests suggested an anaphylactic purpura, preparations of egg white, mayonnaise, foie gras, and lobster were scratched into the skin no reaction. Similarly, intradermal reactions with milk, tuberculin, Dmelcos, antistaphylococcic vaccine remained negative, as well as attempts to find a possible focal infection. The intake of foie gras on Feb. 20 did not bring any of the reactions characteristic of Vidal's digestive hemoclasia, nor any rash.

However the patient—who had been kept at normal temperature—ate on Feb. 6, at noon, lobster cocktail sauce and, in the evening, some foie gras. On the next morning, the purpuric stripes appeared at the base of the neck and on the anterior aspect of the forearms, the latter spots were surrounded by an area of congestion without pruritus. The eruption induced on February 6 and 7 was much milder than the previous ones. This was the last of the purpura of this patient.

On Feb. 14, Paul and Bunnell's reaction: $1/16+++$, $1/32++$, $1/64+$

COMMENTS

Both cases reported had a purpuric eruption.

In the first one, the eruption was symmetrical and made up of innumerable petechiae grouped in cluster, in maplike areas 0.5 to 2 cm. in diameter, separated by areas of almost normal skin. This relapsing purpura simplex had a protracted course or at least a subacute one. The etiology remained mysterious, as well as the cause of the different attacks. However, outside any purpuric attack, the vascular fragility test was twice strongly positive, quantitatively and qualitatively, but only in those cutaneous areas where the previous eruptions had spontaneously occurred.

In the second patient, the eruption, also symmetrical, was formed by rather homogenous hemorrhagic streaks not resulting from the coalescence of smaller petechial elements. The only real petechiae were observed on the soft palate. The etiology of the syndrome probably was alimentary. However, it is noteworthy that the cuti-reactions with the suspicious foods remained negative, as well as Vidal's tests of digestive hemoclasia, and that the purpura simplex of this patient occurred at the same time as an attack of infectious mononucleosis. The vascular fragility test was completely negative at the place of the purpuric spots and outside them.

Thus, in one of the two reported cases of purpura simplex, a strongly positive quantitative and qualitative vascular fragility test was present.

In the other, the vascular fragility test was completely negative.

In order to explain the different behavior of the vessels of the two patients during venous stasis, one might consider the different nature of the two cases of purpura, as also evidenced by differences in the clinical course and in the purpuric eruption.

This simple interpretation is probably accurate.

Nevertheless a case of constitutional athrombopenic hemorrhagic purpura published by one of us in 1929 (Roskam⁸) might be taken as an argument against it.

For this patient we noted on April 5, 1927, at the time of his admission to the hospital:

Tourniquet test after 15 minutes of compression at 70 mms. of mercury with the blood pressure machine: there appeared below the right elbow several large petechiae measuring 1–3 mms. About 50 were seen on the anterior aspect, 40 on the posterior aspect of the forearm. Under the same conditions, the test being repeated twice, no purpuric elements were seen over the left forearm. On April 29 we noted

"Tourniquet test after 15 minutes of compression of the arm at 80 mms of mercury, identical numbers of petechiae appeared over the right forearm as had been noted on April 5. The left forearm at this time showed a very marked purpuric eruption with enumerable punctate petechiae. 195 petechiae were present on the anterior aspect of the left forearm together with 6 ecchymoses of about 5 mms in diameter. Posteriorly 175 petechiae of about 1 mm in diameter were seen. Tourniquet test after 15 minutes of compression at a pressure of 100 cu mms of mercury, an intense purpuric eruption about the same both in the right and left arms occurred. Numerous petechiae were seen. These extended over the dorsum of the hands and over the fingers."

We have thus observed a case of constitutional athrombopenic hemorrhagic purpura with, during an acute period, a vascular fragility test quantitative +, qualitative ++ on the right side, completely negative on the left side, a few days later, quantitative +, qualitative ++ on the right side, quantitative and qualitative +++++ on the left. Two years later, without hemorrhagic episode, the vascular fragility test was strongly and equally positive on both sides.

This observation indicates the great variability of the vascular fragility test at different times, and also at different sites, in symmetrical areas of the skin in a case of chronic hemorrhagic purpura.

Together with the two new cases reported in this paper, it shows the complexity of the factors producing the purpuric eruption. The appearance of cutaneous hemorrhages is in no way a simple phenomenon and its mechanism is still unknown. The observations of Bedson has shown that the experimental induction of petechiae and hemorrhages sometimes requires the cooperation of a hemic and a vascular factor. Reilly, Rivallier, Compagnon, Laplane, and Du Buit,⁶ later confirmed by Frumusan,³ have demonstrated the role of the autonomous nervous system in animals in the production of some hemorrhagic lesions of the gastrointestinal tract. These very interesting experiments do not, however, afford a satisfactory explanation of the clinical observations concerning the apparition of purpura.

We hope that this paper will draw attention to this important problem, and that it will make experimenters and clinicians conscious of the inconstancy and variability of the vascular fragility test.

SUMMARY

Two unusual cases of purpura simplex raise the problem, as yet unsolved, of the pathogenesis of the purpuric eruption. Together with a previous observation of hemorrhagic purpura made by Roskam, they show the inconstancy and variability of the vascular fragility test.

THE VALUE AND THE LIMITATIONS OF THE COAGULATION TIME IN THE STUDY OF THE HEMORRHAGIC DISEASES

By ARMAND J. QUICK, PH D, M D, RENE HONORATO C, M D, AND
MARIO STEFANINI, M D

THE DETERMINATION of the coagulation time of the blood is among the most empirical procedures routinely employed in the clinical laboratory, and is one most prone to be misinterpreted. In a critical evaluation of this test, one must consider first the mechanics of the procedure and second the physiological aspects, which require a translation of an *in vitro* observation into a probable *in vivo* behavior that is coordinated with other factors bringing about hemostasis. For this task a short historical survey is helpful since one can thereby acquire a knowledge of the evolution and development of the tests of coagulation time that are now in common use.

Although delayed coagulation of shed blood in various conditions was observed even in antiquity, there appears to have been no formal clinical test until 1878 when Vierordt¹ devised a procedure consisting of drawing a horse hair through blood in a capillary tube and observing first the point when fibrin threads adhered and again when the hair was free. In 1893 Wright² determined the coagulation time by filling capillary tubes with blood and noting the time when the contents could no longer be discharged by blowing. This investigator appears to have been the first to state specifically that the coagulation time of hemophilic blood was delayed. Brodie and Russell³ three years later described a special instrument called a coagulometer in which a hanging drop of blood observed under a microscope is played upon by a current of air and the time determined for arresting the movement of erythrocytes. In 1898, Hayem⁴ introduced the simple procedure of putting venous blood in a test tube and noting how much time was required before a sufficient clot was formed to permit tilting without a flow of blood. Fifteen years later Lee and White⁵ employing the same principle devised a test which with minor modification has become the most widely used and most acceptable method for estimating the coagulation time. It is this test which is critically studied in this paper.

Several other tests should, however, be mentioned because they have in the past been employed extensively. Two of these methods were described in 1904. The first was Burker's⁶ in which a fine glass rod is passed repeatedly through a drop of blood thereby catching the first strands of fibrin formed. The other was devised by Sabrazès⁷ who filled capillary tubes with blood and at regular intervals of time broke off a short piece until a fibrin thread appeared between the severed sections. Fuld and Schlesinger,⁸ in 1912, introduced another approach, blood was placed in a U-tube and the movement of a metal bead observed as the tube was gently tilted and the moment timed when the density of the clot fixed the bead. A modification of this method by Hedenius⁹ is still widely used especially in the Scandinavian

countries For a detailed and complete review of this subject, Nygaard's monograph¹⁰ should be consulted

Interpretation of the coagulation time All the common procedures for determining the coagulation time are based on timing the interval between the removal of the blood from the vessel and the formation of sufficient fibrin to meet an arbitrarily designed end point The objective of every test is to measure the intrinsic coagulative power of the blood Obviously therefore, trustworthy results can be obtained only by performing the test under constant and rigidly controlled conditions and by excluding all outside agents that influence the coagulation reaction Of the latter, tissue juice is by far the most important since it contains thromboplastin It is therefore of utmost importance to exclude all traces from the specimen of blood used for determining the clotting time Obviously, blood obtained by skin puncture (capillary blood) is utterly unsuitable since not only does it contain an appreciable amount of tissue fluid, but even more serious, the amount cannot be controlled Thus Christie¹¹ demonstrated that there were variations in the clotting time of the different drops of blood collected from the same puncture, and Lee and White⁵ cite the example of a hemophilic blood which had a coagulation time of 50 minutes for venous blood and only 5 minutes for capillary blood It must be emphasized that the coagulation time of capillary blood, irrespective of the method used, is worthless and unreliable for clinical purposes Even in taking blood by veni-puncture enough tissue thromboplastin may occasionally gain entrance to reduce significantly the coagulation time as Jaques and his co-workers¹² have recently demonstrated It is not unusual to obtain a coagulation time of 8 to 10 minutes in a hemophilic subject, whose true coagulation time is 1 hour, merely by causing slight trauma in drawing the blood

Standardization of the coagulation time There is a distinct need for a simple and uniform procedure In the United States the Lee-White test is gradually replacing the other methods This procedure is simple and yields as much and as accurate information as any test of coagulation so far devised, but unfortunately the test has not been rigidly standardized and at present there is no strict uniformity in the details of the procedure

In order to devise a standard procedure, it is necessary to consider the more important factors that influence the coagulation of blood in a test tube They are (1) temperature, (2) size of tube and (3) the nature of the surface of the tube

Temperature Since the coagulation of blood involves chemical and enzymatic reactions, it is obvious that the temperature must significantly influence the speed of the process This is clearly demonstrated by the results in table 1 in which the clotting times obtained at 22° C and 37° C are recorded The marked effect on hemophilic blood is particularly noteworthy Similar observations have been recorded by Park and Stetson¹³ The need for adopting a constant temperature at which the determination is carried out is evident Body temperature (37° C) seems most desirable since it is at that temperature that coagulation takes place physiologically An ordinary vacuum bottle filled with water at 37° C serves as a handy water bath for carrying out the coagulation time test The practice of performing the test at room temperature should be abandoned since the temperature range in many laboratories may be from 20° C to 30° C and this causes considerable difficulty and confusion in interpreting the clotting time and in deciding whether it is within normal limits

The size of test tube The original Lee-White procedure specified the use of a Widal tube 8 mm in diameter, but test tubes of varying sizes are now employed To show the effect of size of tube, the clotting times of bloods in test tubes with internal diameters of 8 and 11 mm were compared Curiously, normal blood clots more rapidly in the smaller tube while hemophilic blood clotted considerably faster in the

larger test tube (table 1). A possible explanation is that the clotting time is influenced by both the area of the surface in contact with the blood and the surface of the blood exposed to air. In normal blood the disintegration of platelets is probably roughly proportional to the amount of foreign surface, and therefore the smaller the tube the greater the surface and the faster the disintegration of platelets. In hemophilic blood the platelets in contact with a foreign surface do not readily undergo lysis and therefore the contact of the blood with air has a more predominating effect. The influence of exposure to air is particularly well demonstrated by normal plasma deplateletized by high centrifugation. Coagulation begins at or near the air-plasma interface and travels downward.

Since the size of tube definitely influences the speed of coagulation, it becomes necessary to standardize by selecting a fixed size of tube. Since nearly every laboratory is well supplied with serological test tubes (13 x 100 mm) and since this is a convenient size both for handling and cleaning, it seems logical to select this tube for the test.

TABLE 1—*The Effect of Temperature, Size of Test Tube and Surface of Test Tube on the Coagulation Time*

		Coagulation time in minutes					
Subject	Type of test tube	Glass*	Glass*	Glass*	Lusteroid	Collodion coated	Silicone coated
	Internal diameter	11 mm	11 mm	8 mm	13 mm	11 mm	11 mm

	II	76	25	31	190	240	340

* Pyrex

Nature of the surface of the tube. Blood clots fastest in glass as can be seen from the results in table 1. In a lusteroid (a synthetic plastic) tube, coagulation is definitely delayed, and in collodion coated tubes the retardation is even more marked. Silicone (Dry Film) coating, however, is the most effective artificial surface known for preserving the fluidity of blood.

A glass test tube is best suited for determining the coagulation time, since as much information is obtained as would be by employing any other type of tube, and it obviates the long waiting period which is always undesirable in a clinical laboratory.

Recommended procedure for determining the coagulation time. Blood is drawn by veni puncture preferably with a No. 22 needle, into a dry syringe. If the determination cannot be made immediately, a syringe coated with silicone (Dry Film)* should be used, and the blood kept in the syringe until the operator is ready for the test. In drawing the blood the tourniquet should be applied just prior to the puncture. If blood is not obtained immediately and without trauma, another vein should be selected and a new puncture made. One cubic centimeter of blood is transferred into each of 2 scrupulously cleaned test tubes (Pyrex 100 x 13 mm). Since the test tubes are apt to vary slightly in size, only tubes having an internal diameter of 11 mm should be selected. The tubes are immediately placed in a water bath kept at 37°C. A vacuum bottle fitted with a cork having a hole in which the test tube can be inserted serves as a handy portable water bath. The tube is gently tilted every 30 seconds and the end point taken as the moment when on tilting no flow of blood is any longer observed. The normal range is 5 to 10 minutes with the majority of bloods clotting between 6 and 8 minutes.

* Manufactured by the General Electric Company and marketed as Dry Film No. 9987

It should be emphasized that the end point selected is arbitrary and does not mark the time of complete coagulation. Unconverted fibrinogen may still be demonstrated. A convenient way to measure incipient coagulation is to insert a glass rod coated with collodion into 1 cc of blood and then withdraw it gently every 30 seconds. A fine thread of fibrin marks the beginning of coagulation. In normal blood, coagulation usually begins in $3\frac{1}{2}$ to 4 minutes and is complete in 10 minutes, whereas in hemophilic blood coagulation may begin (to cite a specific observation) in 10 minutes but require 2 hours more before enough fibrin is formed for a solid clot. The tube with the glass rod should not be used for determining the final coagulation time.

A NEW THEORY OF BLOOD COAGULATION AND ITS BEARING ON THE COAGULATION TIME

As the result of recent studies,¹⁴ evidence has been obtained to show that platelets do not furnish thromboplastin, but in their disintegration liberate an agent, probably an enzyme, that activates thromboplastin which occurs in the plasma as a precursor and for which the term, *thromboplastinogen*, has been proposed. It is probably identical with the antihemophilic globulin of Minor and Taylor and the prothrombokinin of Lenggenhager.

According to this new concept, the first step in coagulation can be expressed as follows

The activated thromboplastin reacts immediately

The first and third equations are enzymatic, whereas the second is stoichiometric. Thus, even a small number of platelets are sufficient to activate enough thromboplastin to furnish a quantity of thrombin that will coagulate blood within the normal period of time. Such a quantity of thrombin may, however, be entirely inadequate, as will be discussed later, to meet the hemostatic requirements. To understand the significance of the coagulation time, it should be remembered that normal human blood could clot in 12 seconds if it had an optimum amount of thromboplastin and that furthermore, the curve correlating the coagulation time and the concentration of thromboplastin is a hyperbola with both asymptotes zero. This explains why the shortening of a coagulation time from 1 hour to 5 minutes can be brought about by an extremely small quantity of thromboplastin. The amount of thrombin formed depends not on the coagulation time but on the quantity of prothrombin, thromboplastin, and calcium in the plasma and this can be looked upon as the key to a better understanding of several important hemorrhagic diseases which will be considered in this presentation.

The coagulation time may be prolonged in four well known diseases or conditions: hemophilia, hypoprothrombinemia, afibrinogenemia and heparinemia. It is possible that a delayed coagulation may occur in other conditions, but these have not been studied sufficiently to permit critical analysis. Hypercoagulability remains a vague and as yet meaningless term.

THE COAGULATION TIME IN HEMORRHAGIC DISEASES

Hemophilia With the exception of complete incoagulability of the blood as encountered in afibrinogenemia, the most prolonged coagulation times are observed in hemophilia. A coagulation time of one hour is not unusual, but a time of two hours or more is rather infrequent, provided the test is done carefully and at 37° C. It has been found in recent studies that the coagulation time of a hemophilic may be surprisingly constant for a relatively long period of time. Thus, the coagulation time of one subject has remained about 55 minutes with few exceptions during the past 18 months. Although it has been brought to normal several times with plasma transfusion it has always promptly returned to this rather fixed value. The same constancy has also been found in other hemophilics, but in no instance has the period been long enough to be significant.

To understand the coagulation time in hemophilia, it is necessary to understand the basic defect in this disease. In a recent study¹⁴ it has been found that hemophilic blood is almost completely devoid of thromboplastinogen, and even after all the fibrinogen has coagulated, no demonstrable consumption of prothrombin has occurred.* All the coagulation is due therefore to a minute quantity of thrombin which is formed and which, because it is an enzyme, can convert all of the fibrinogen to fibrin in a relatively short time. The minuteness of the quantity of thromboplastin which can bring about a normal coagulation time is clearly demonstrated by the following experiment.

A stock extract of thromboplastin prepared by mixing 0.2 gm. of dehydrated rabbit brain in 5 cc. saline, was diluted 1 to 1000. On adding 0.1 cc. of this diluted thromboplastin to 1 cc. of a hemophilic blood which had a coagulation time of 2 hours and 15 minutes, the time was reduced to 5 minutes. This 0.1 cc. of thromboplastin contained only 2.5 gammas of solid material, of which a large fraction was inert. Obviously, the amount of thrombin formed must have been extremely small, yet it coagulated the blood in 5 minutes. The conversion of prothrombin, however, was so small that it could not be demonstrated.

From the results observed in hemophilia and in hypoprothrombinemia it seems definite that hemostasis is not dependent on the clotting time but on the quantity of thrombin supplied during the clotting process. In hemophilia little thrombin is formed since the plasma lacks the thromboplastin precursor. Even if the plasma contains enough thromboplastinogen to cause a normal coagulation time, it may not be sufficient to supply enough thrombin for the hemostatic needs. This explains why a normal coagulation time may be found in known hemophilics suffering from repeated hemorrhages. In a limited number of such patients, the senior author could demonstrate no consumption of prothrombin after coagulation had been completed. Such patients are a problem to the surgeons since the normal coagulation may create a false sense of security. Furthermore, not every measure which reduces the coagulation time of a hemophilic is necessarily effective in controlling hemorrhage. Just as the effectiveness of vitamin K cannot be established

* A new procedure named the prothrombin consumption test has been developed. It consists in determining (by the senior author's method) the prothrombin remaining in the serum 1, 3, and 24 hours after the blood has clotted.

by the coagulation time but only by the decrease in the prothrombin time, so the assay of any antihemophilic agent cannot be made with an absolute degree of certainty by the coagulation time, but will probably require the measurement of the prothrombin consumption

The coagulation time is obviously of limited value in hemophilia either in the diagnosis or in the treatment. A prolonged value is suggestive of hemophilia provided other causes are ruled out. A normal coagulation time does not exclude a diagnosis of hemophilia. A history of bleeding and a markedly poor consumption of prothrombin during coagulation appears to be much more reliable evidence on which to base a diagnosis.

The coagulation time, is, however, of some practical and theoretical value. A hemophilic with a coagulation time that is nearly normal usually has mild attacks of bleeding and only encounters serious trouble when relatively large vessels are damaged. The severity of the bleeding tendency appears to be relatively independent of the coagulation time when the value of the latter exceeds 15 to 20 minutes. In three hemophiliacs having average coagulation times of 25, 55 and 120 minutes respectively, the frequency and severity of the bleeding episodes during a period of observation of 6 months, was roughly the same. Theoretically, the coagulation time is of value since it offers the only means to grade the severity of the hemophilic defect. Thus the difference in availability of thromboplastin between the three hemophiliacs mentioned is so small that no other test, including the prothrombin consumption, can detect the difference.

The coagulation time has, it should be mentioned, served not only in establishing the presence in plasma of an antihemophilic agent, but has enabled Minot, Taylor and their associates¹⁵ to concentrate it. They wisely depended not so much on a transient lowering of the coagulation time but on a sustained normal value.

Hypoprothrombinemia Prior to the advent of vitamin K, it was very puzzling to the surgeon why the jaundiced patient bled postoperatively in spite of a normal coagulation time. The senior author, on the basis of his early studies on vitamin K, concluded that the hemorrhagic danger level was indicated by a prothrombin time of about 25 seconds, which corresponds in man to a prothrombin activity of 20 per cent of normal. At this level the coagulation time is so little increased that unless the test is done with great care it escapes detection, since it is still well within the normal range. In fact, it has been found¹⁶ that in dogs an increase of the prothrombin time from the normal of 6 seconds to 60 seconds is accompanied by a change of the coagulation time only from $3\frac{1}{2}$ to $5\frac{1}{2}$ minutes, i.e., an average increase of only 2 minutes. Even with extremely low concentrations of prothrombin, the coagulation time is rarely as prolonged as in moderately severe hemophilia. At very low levels, the prothrombin time and the coagulation time tend to become identical. Thus, on reducing the prothrombin in a dog with dicumarol until the prothrombin time was 20 minutes, a coagulation time of 19 minutes and a clotting time for recalcified plasma of 30 minutes was obtained. The likely reason for such a result is that the limiting factor is prothrombin and that under such circumstances the thromboplastin of the plasma is adequate, and therefore additional amounts of the latter have no further effect.

Early in the work on toxic sweet clover poisoning, one of us¹⁷ discovered that a heart puncture in a rabbit with a reduced prothrombin caused fatal hematopericardium. This serves, therefore, as a useful means to study hemostatic effectiveness, and

TABLE 2.—*The Relationship of the Coagulation Time, Clotting Time of Recalcified Plasma, and Prothrombin Time to the Hemostatic Breakdown*

* Control the other five rabbits were given 2 mg per kg of body weight of dicumarol daily by stomach tube

† Blood was obtained from the median artery of the ear with a silicone coated syringe, which probably accounts for the long normal coagulation time

‡ The heart punctures were made with a No. 21 needle and always approximately in the same position

In table 2 a correlation is made between the prothrombin time, coagulation time, and the hemostatic breakdown. A study of these results clearly shows that when the prothrombin time is less than 19 seconds the animals' blood could prevent cardiac bleeding. With a prothrombin time of 24 seconds or more, hematopericardium

invariably occurred. While there was a slight increase in coagulation time, no clear cut relation between it and fatal hemorrhage could be found. Interestingly, one of us has observed a series of cases with congenital hypoprothrombinemia and has found that those with a prothrombin time of 16 seconds showed no hemorrhagic tendency, two cases with a prothrombin time of 19 seconds showed a distinct bleeding tendency, and one case with a value of 30 seconds showed a very severe hemorrhagic condition.

Obviously the coagulation time is of little or no value in the study of hypoprothrombinemia. It cannot be used for controlling dicumarol therapy. Again basically the fact is brought out that hemostasis depends on the amount of thrombin formed, and when the prothrombin is reduced to about 20 per cent insufficient thrombin is furnished for stanching.

Afibrinogenemia When total incoagulability of the blood is found, afibrinogenemia should be suspected and a qualitative test for fibrinogen made. Recently, Pinniger and Prunty¹⁸ demonstrated experimentally that the prothrombin time remained approximately normal in the blood of their patient until the fibrinogen fell below 50 mg per 100 cc of plasma, and that the Lee-White coagulation was 5 minutes when the fibrinogen concentration was as low as 30 mg. It is obvious that the coagulation time has little practical value in this hemorrhagic condition except in the initial detection of a coagulation defect.

Heparinemia Animals, particularly dogs subjected to peptone or anaphylactic shock, respond by an outpouring of histamine and heparin into the blood, and by a marked thrombocytopenia. The resulting heparinemia may be so great that the blood is rendered incoagulable. In man, the appearance of heparin in the blood has not been unequivocally demonstrated although there is a good probability that it can occur. The increase of the coagulation time is not necessarily proportional to the concentration of heparin. The latter can be much more accurately determined by titration with progressive dilutions of a standard thrombin solution.¹⁹

The therapeutic use of heparin in the prophylaxis of thrombosis is successfully controlled by the coagulation time, but this is entirely on an empirical basis, since it has not been accurately determined how much heparin is needed for this purpose. It is probable that the effective action of heparin consists in neutralizing thrombin, and thus reduces the effective quantity of the latter.

From the foregoing discussion, it becomes clear that the coagulation time has limited value in the study of the known hemorrhagic diseases. It has, however, an important function in the possible discovery of new hemorrhagic diseases. On finding a prolonged coagulation, a concise diagnosis can be made only by specific tests such as the prothrombin time, and the prothrombin consumption test. A little over a decade or two ago, hemophilia was the waste basket for nearly all hemorrhagic diseases characterized by a coagulation defect. Since then hypoprothrombinemia, afibrinogenemia, and heparinemia have been recognized as separate entities. It is highly probable that other hemorrhagic conditions having a prolonged coagulation time exist but thus far have not been recognized and defined because of a lack of suitable methods of study.

SUMMARY

The coagulation time is a measurement of the intrinsic power of the blood to convert fibrinogen to fibrin. It is an empirical test no matter how performed, and therefore in order to be reliable requires that the test be done on venous blood under strictly controlled conditions. A recommended procedure is outlined in detail.

The coagulation time is prolonged in hemophilia, hypoprothrombinemia, afibrinogenemia and heparinemia. In hemophilia, the coagulation time theoretically is a measure of the severity of the disease but practically is of limited value since the coagulation time may be within normal limits in some patients, the prothrombin consumed in the coagulation of hemophilic blood is therefore a better guide for diagnosis. The coagulation time in hypoprothrombinemia is relatively little prolonged until a drastic reduction occurs. The test is therefore of no value for establishing a hemorrhagic condition in hypoprothrombinemia. In afibrinogenemia the blood is incoagulable. A small amount of fibrinogen restores the coagulation time to normal.

The presence of heparin increases the coagulation time. The test is therefore useful in controlling the therapeutic action of this drug.

The senior author, in making a survey of the literature on hemorrhagic diseases in preparation of his monograph, was impressed by the significant and diverse contributions which Dr. George R. Minot made to this field of medicine. We feel honored to contribute this study to the collection of papers offered as a fitting tribute to Dr. Minot, who has so successfully and productively combined science and clinical medicine.

THE ACTIVATION OF PROTHROMBIN, WITH SPECIAL REFERENCE TO "THROMBOPLASTIC ENZYME" (TRYPTASE)

By JOHN H. FERGUSON, M D , BURTON L. TRAVIS, B A , and
EARL B. GERHEIM, M S

THE BASIC mechanisms whereby plasma prothrombin is converted into active thrombin, in order to coagulate fibrinogen solution to fibrin clot, can be shown by an experimental analysis of the isolated phases of clotting in vitro.²³ The theoretic goal would be to isolate *prothrombin* in a chemically pure state and subject it to test reactions in order to learn the various factors which participate in its activation to thrombin. In actual practice, however, the criteria of purity are difficult to define, particularly in view of the fact that mere traces of certain factors¹⁴⁻²⁰ suffice to cause a considerable degree of activation if operating over a long enough period. Such "trace impurities" quite fail to show up in the usual criteria, e g , constant solubility,⁶¹ unicomponent electrophoretic pattern and isoelectric point,⁶² and other data valid in protein chemistry.⁷ It is most necessary, therefore, to supplement the examination of "purified" clotting agents with a series of sensitive tests for the presence and modes of action of these impurity factors.

Seegers and colleagues⁶¹ have carried the difficult problem of prothrombin purification to a point which is very satisfactory from the viewpoints of biochemistry and physiologic potency. Through the courtesy of Dr. Seegers, we have been supplied with a number of these prothrombin preparations, the experimental analysis of which provides the bulk of data herewith reported. It must be emphasized that the results of these tests in no wise detract from the signal advance which these prothrombins represent in terms of potency and of freedom from all but traces of contaminants.

I REAGENTS

1. *Borate buffer* (buff.) 45 vol. 2.5 per cent H_3BO_3 , 45 vol. 0.5 per cent NaCl, 10 vol. 4 per cent $Na_2B_4O_7 \cdot 10 H_2O$ (a simplification of the formula given by Burdon²) is used as solvent and diluent (e g , to constant volumes) throughout. It maintains a constant pH of 7.7 and largely controls the ionic strength of all our solutions. Its mild bacteriostatic properties are valuable in permitting the prolonged keeping and observation of the protein solutions, e g , thrombin mixtures, for several weeks and fibrinogen for many days at room temperature, and fibrinolytic tests (and controls) for similar periods at 37°C, with only a very occasional contamination by molds and bacteria (e g , T_2^* , table 8), even without meticulous sterilization of glassware, etc., and more than simple corking of tubes to exclude dust and prevent evaporation.

2. *Fibrinogens* (a) *Bovine plasma Fraction-I* (B F), Armour Lab., courtesy of Dr. J. B. Lesh, has proved to be a highly satisfactory fibrinogen preparation for quantitative clotting-time studies. An 0.5 per cent solution in borate buffer requires filtration of only a trace of insoluble fibrin-like material. Solutions should be kept at cool room temperature (20°C), not in the icebox, since the protein solubility is reduced.

From the Department of Physiology, School of Medicine, University of North Carolina, Chapel Hill,
N C

by borate at low temperatures. The insignificant traces of thrombin which form in solution may cause a slight fibrinous flocculation in four to six days (average). Owing to the broad zone of optimal fibrinogen concentration for clotting (Table 2), this trace of fibrin may be filtered off and the solution used for a day or two longer. However, this is not recommended in tests of the highest accuracy and it is unnecessary, since a new batch of B F solution can be relied on to give identical clotting-time values with similar thrombin solutions. Rigid tests, with added CaCl_2 and thromboplastin, show a trace of prothrombin, but this requires many hours to activate and then produces a mere trace of clot. By no criteria can these facts be regarded as in any way interfering with the data to be presented. Armour's B F is significantly free from trypsin, tryptogen, and enzyme inhibitors (infra). It is stated to yield about 60 per cent of fibrinogen (clottable N).

(b) *Human plasma Fraction-I* (H F) or antihemophilic globulin (crude,⁴⁵ Harvard Laboratory, courtesy Drs. E. J. Cohn, J. T. Edsall, G. R. Minot and colleagues), has a similar (60 per cent) fibrinogen content, a somewhat (but not unduly) greater contamination with fibrinous and thrombic impurities, and a trace of active protease (trypsin), together with significant amounts of its precursor (tryptogen),

which is best activated with Garner and Tillett's (1934) streptococcal agent now renamed streptokinase.⁶ In the present studies, H F is used only as a source of plasma protease (q.v.).

3. *Prothrombins*. The data reported in this paper are obtained by the use of several prothrombin preparations purified to various stages of the method of Seegers, Loomis, and Vandenberg.⁶¹ PRO A was prepared, by ourselves, from citrated dog plasma, while the others, bovine PRO B-PRO H, were supplied by Dr. Seegers. A summary of data on these materials is appended in table 1 and their coagulant properties are discussed fully in the text. Brief allusion is also made to older Howell-type¹⁶ crude prothrombin, precipitated by acetone from heat defibrinated (56 C) dog plasma, and dried on filter papers.

4. *Activators of prothrombin*. (a) *Calcium salt* (Ca). M/10 CaCl_2 is prepared from stock M/1 (11.1 per cent) CaCl_2 by dilution, preferably with borate buffer.

(b) *Cephalin* (ceph.) the purified phospholipid isolated from brain¹⁶ is briefly alluded to in the text.

(c) *Thrombokinase or thromboplastin* (tpln.) the preparations repeatedly used in these studies, are filtered (glass wool) borate buffer suspensions of several commercial thromboplastins, designed for use in plasma prothrombin assay tests, e.g., tpln. A Squibb's (rabbit brain), tpln. B Difco's (rabbit brain), tpln. C Sharp and Dohme's (horse brain). On a few occasions we used frozen dog brain (tpln. D). The universal finding of a trace of proteolytic enzyme in all these crude thromboplastins is noteworthy.

(d) *Thromboplastic enzyme* see *Proteases*.

5 *Inhibitors of Prothrombin Activation* (a) *Citrate* (citr) 1/10 vol 4 per cent trisod citrate (hydrated) is optimal for (1) plasma preservation and (2) inhibition of 'spontaneous' activation of prothrombin solutions (see text)

(b) M/1 *oxalate* ($K_2C_2O_4$) or *citrate* ($Na_2C_6H_5O_7$), added to an equal vol of thrombic mixture, are best for progressive inactivation of thrombin-¹ intermediary (see text)

(c) *Heparin* (hep) 1 to 10 dil (borate buffer) of Lederle's Sod heparinate (1 per cent) gives a solution containing 100 Toronto units per cc, which does not alter the pH of the buffer

(d) *Trypsin inhibitors* see *Proteases*

6 *Thrombin* For following fibrinogenolysis (e g, table 13A) or clot-lysis, when the protease is to be studied in the fibrin, it is necessary to use an enzyme-free thrombin. A convenient preparation for this purpose is a 1 per cent solution of lyophilized rabbit hemostatic globulin²¹ (h g), Lederle Laboratory, courtesy Dr I A Parfentjev.²¹ Some of the products, especially those supplied in solution for topical hemostasis,²² are less suitable, however. Other commercial thrombins, viz (TU) Upjohn's, courtesy Dr J T Correll, and (TBD) Parke Davis, courtesy Dr E A Sharp,²³ are alluded to in table 20

TABLE 2—Clotting-times in Relation to Concentration of Fibrinogen

C t (in seconds), at 25 C, for 0.5 cc fibrinogen (B F-strengths* cited) + 0.5 cc thrombin (h g, 1%)—see *Reagents*

Conc (%)*	20	10	0.5	0.2	0.1	0.05	0.02	0.01
Clotting-time (in seconds)	6	5	5	6	7	10	47	115

* Grams of original material (B F 60 per cent clottable fibrinogen) per 100 cc

TABLE 3—Clotting-times in Relation to Concentration and Age of Thrombin Solution

C t (in seconds), at 20 C, for 0.5 cc B F (0.5%) + 0.25 cc thrombin (T)*

Rel T conc (%)	100	50	25	10	5	1	0.5
	(Time in seconds)						
Aged ¼ min	4	8	11	22	41	84	117
30 min	4	8	11	22	48	104	194
60 min	4	8	11½	24	54	130	205

* T (100%) = 3-day old mixture of 4 cc PRO G (0.4%) + 5 cc buff + 0.5 cc tpin D + 0.5 cc $CaCl_2$ (M/10)—see T₆, table 8

7 *Proteases* (a) *Active enzyme* (1) *Pancreatic trypsin* (a) *crystalline trypsin*, from pancreas, courtesy Dr M Kunitz²⁴ (Rockefeller Institute, Princeton) is desirable for such special purposes as distinguishing effects from those of chymotrypsin. However, for most practical purposes, e g 'standard' for routine protease assay by the fibrinogenolytic method,²¹ (b) *commercial trypsin* (Fairchild Bros and Foster), will suffice. This trypsin (tryp) in the form of a 2 per cent extract made with equal vols of glycerol and borate buffer (cf Burdon²⁵), filtered, and stored in the ice-box, is the stock solution from which standard dilutions are freshly made (with borate buffer) immediately before use. One trypsin UNIT is the fibrinogenolytic potency (for 0.25 per cent B F) of 0.01 mg (per cc) of our standard trypsin. Lysis tests are conducted in the warm room (37 C) or water-bath (39 C)

(2) *Trypsin preparations* (a) The Harvard human plasma fraction (III-3), supplied through the courtesy of Dr J T Edsall,²⁶ has considerable proteolytic properties, together with much thrombic activity (see text), (b) *Dog plasma trypsin* (tryp D) is prepared by a method we have not yet perfected (particularly from the point of view of stability of the enzyme preparation) but the product may be characterized as able to give complete fibrinogenolysis in 3 to 5 minutes and clot-lysis in 9 to 10 minutes at room temperature, when using 0.5 per cent B F, or fibrin clot therefrom, as substrate, (c) *Crystalline*

human serum albumin (H S A) and *crystalline bovine serum albumin* (B S A), Harvard Laboratory, courtesy Dr J T Edsall,²⁷ are found to be contaminated with a trace of active tryptase

(b) *Preparations containing enzyme-precursor (tryptogen)* Many plasma protein fractions contain, in addition to traces of active tryptase, varying amounts of tryptogen (enzyme-precursor), which can be activated by shaking with chloroform,²⁶ or, better, by using streptokinase⁶ (v infra)

(1) *Human plasma Fraction-I* (H F), v supra, and the more refined (85-90 per cent clottable) but less stable (2) *human fibrinogen* (H Fb³³), products of the Harvard Laboratory (courtesy Dr E J Cohn and colleagues), are representative of this group, and so are (3) various $(\text{NH}_4)_2\text{SO}_4$ -pptd fibrinogens which we prepare from dog plasma (D Fb) On the other hand, Armour Laboratory bovine fibrinogen and the more satisfactory fibrinogen precipitated from bovine Fraction-I (B F) by $(\text{NH}_4)_2\text{SO}_4$ are as enzyme-free as the cruder fraction³³

(d) *Tryptase inhibitors* Through the courtesy of Dr M Kunitz (Rockefeller Institute, Princeton), we received some *crystalline pancreatic trypsin-inhibitor* (T I³²) and *crystalline soybean trypsin-inhibitor* (S B I⁴⁴), the highly significant tryptase- and thromboplastin-inhibiting properties of which are discussed in the text

II QUANTITATIVE METHODS

Owing to lack of methods for direct chemical analysis in dealing with such complex proteins as fibrinogen and prothrombin (or thrombin), reliable assay methods necessarily involve the whole coagulation reaction *Clotting-time* (c t), measured under carefully standardized conditions,¹⁵ is the best and only currently practical solution to the problem of quantitative estimation of thrombin (*activated* prothrombin)

Experimental conditions ⁶² Being colloidal reactions,²⁶ the clotting processes are influenced by (1) temperature, (2) pH, (3) salt content, (4) concentration (dilution) of specific factors (v. infra), and (5) adsorption and related colloidal phenomena ²⁷ In the last category are (a) effect of wettable surfaces, e. g., the well-known ability of blood to clot quicker in glass than in paraffined,³⁶ plastic,⁶³ or silicone treated⁴¹ tubes, and (b) the clot-riding (second phase) or fibrinoplastic effects of a wide variety of nonspecific colloids, e. g. kaolin,⁵⁶ gum acacia,⁶³ salmine,¹⁸ etc ⁵⁶ The first step, therefore, is to standardize these experimental conditions

Fibrinogen concentration and clotting-time Table 2 shows the varying clotting-times when a given thrombin solution (1 per cent h. g.) is added to an equal volume (0.5 cc.) of a series of fibrinogen (B. F.) dilutions. Confirmatory of many older data,⁷⁰ there is found a broad optimum which, for this and similar fibrinogens,

FIG. 1. CLOTTING-TIMES AND RELATIVE THROMBIN CONCENTRATION (PERCENTAGE) THE INVERSE LAW (ref. Am. J. Med. 3, 67, 1947)

Clotting-times (sec.) and $1000 - ct$ (sec.) of 1 cc. fibrinogen (0.5% B. F.) + 0.25 cc. thrombin (T)
Temp. 25° C, pH = 7.7 (borate buffer)

T = 2-day old mixture of 8 cc. PRO. C (0.2%) + 1 cc. buff. + 0.5 cc. rpln. A (0.25%) + 0.5 cc. M/10 CaCl_2

lies in the zone of concentrations between 10 and 0.25 per cent. A stable thrombin repeatedly gives identical ct values with a recommended 0.5 per cent B. F. solution every time this is made from the lyophile-dried plasma fraction.

Thrombin concentration and clotting-time Figure 1 shows the progressively shorter clotting-times when a series of thrombin dilutions (0.25 cc. vol.) are tested on a given fibrinogen solution (1 cc. 0.5 per cent B. F.) at pH = 7.7 (borate buffer) and room temperature (25° C). The reciprocals of the clotting-times ($1000 - ct$, sec.), in this particular experiment, give a linear plot, illustrative of the so-called "inverse law."³⁸ In our experience, this law is of limited application in a restricted range of thrombin concentrations and under experimental conditions which it is not possible to define. It does not require rigid mathematical formulation, however, to grasp the fundamental fact that, under standard test conditions, a shorter clotting-time means more thrombin. Thrombin dilution series are given in a number of the following tables to indicate at least the order of magnitude of

the relative amounts of thrombin corresponding to the various clotting-times. The reservations with which we regard any clotting-test system in which the over-all *dilution* of the thrombin is changed led us to make the experiments of table 3.

Thrombin instability during dilution experiments. After complete activation of purified thrombins (see tables), the reproducibility of the clotting-time values in test after test often over a period of several weeks, is (to anyone who has experienced difficulties in keeping the older types of unstable thrombins) truly amazing. Yet any considerable dilution of these excellent thrombins at once introduces a factor of instability. This is frequently apparent in less than a hour at room temperature and more rapidly if the temperature is increased.¹⁵ Table 3 shows thrombin dilution data first obtained immediately ($\frac{1}{4}$ min) after making the dilutions and subsequently repeated, on the same solutions, after $\frac{1}{2}$ hr and 1 hr, respectively, at 20 C. The stronger thrombins show no detectible change but the higher dilutions weaken progressively.

This phenomenon is encountered repeatedly with every type of thrombin studied, including the purest preparations (free from protease, for instance). Moreover, any destructive impurity would be in highest concentration and presumably most active in the stronger solutions. It makes no difference whether buffer or distilled water is used as the diluent. There is no turbidization to suggest denaturation. It can only be surmised that much remains to be learned about the way in which coagulant potency is related to the colloidal structure of the thrombin protein. Over-all *dilution* is undoubtedly a factor of considerable implication in the clotting system.¹⁶ Not knowing the extent of these implications we believe it safest to insist upon always using a definite amount of prothrombin in a *constant volume* of thrombic- and clotting mixtures, since this approximates most closely the natural clotting conditions.

Prothrombin activation data, presented (1) in many tables (4-16) as actual clotting-times (c t), (2) (table 17) as computed thrombin "percentages" (rel T conc), or (3) (figs 2, 3), graphically ("activation curves"), in the course of these studies, are obtained as follows:

A given amount of prothrombin (*fixed* for each series of comparative experiments) is mixed with any activators (and inhibitors) it is desired to study, and the "thrombic mixture" (T) made up to *constant volume* with buffer solution. Actually the most potent activator, usually Ca, is added last and the *incubation period* (i t) recorded from this moment. At various periods, a measured sample (usually 0.25 cc) is removed from the thrombic mixture and added to a labeled 12 mm diameter Wassermann-tube containing the test fibrinogen (usually 0.5 cc 0.5 per cent B F) gently mixed and agitated, and the *clotting-time* (c t) noted with a stop-watch from the moment of mixing to the first appearance of definite fibrin threads.

The *end-point*, in our water-clear solutions, is sharp enough for an accuracy of 5 to 10 per cent, which is often but a fraction of a second. We ignore the earlier point of incipient turbidity and do not trust the later point of solidity (invertibility of tube), since this (a) is read with less accuracy, (b) involves some nonsignificant variables (e.g. diameter of tube) and (c) is often incomplete in the case of extremely weak thrombins.

Since there is only a minor ($\times 3$) dilution factor to check continuing thrombin formation between adding the fibrinogen and the onset of clotting, theoretical objection may be raised on this point. That this is of little practical significance, however, follows from the fact that the most significant clotting-

times are measurable in a matter of seconds after a long (often hours or days) period of activation. Moreover, it tends to enhance the differences between a long clotting-time (due to slow rate of thrombin formation) and a short c t (due to rapid approach toward complete activation). A larger dilution factor, e g., 0.1 cc T + 1.0 cc BF has been tried on a number of occasions without significant benefit. Indeed, it is less suitable for use with very weak thrombins and the volumes are less conveniently measured and pipetted.

We have a number of objections to the use of oxalate or citrate in the fibrinogen,⁹ e g., (1) continued thrombin formation is still possible, especially in the presence of protease (see thromboplastic enzyme), (2) with unduly large amounts of anticoagulant (fig. 2), there may be reversion of incompletely formed thrombin to prothrombin (see section on calcium and thrombin- "intermediary"), (3) there is certainly some second-phase inhibitory effect which may be excessive with very weak thrombins (compare T₁ and T₂, table 8), (4) the c t end-point is less sharp (a) in the case of oxalate, because of opacity due to CaC₂O₄ (whenever calcium is present), (b) in the case of citrate, because of undue translucency at the alkaline pH (7.7) of our borate buffer, although 0.1 to 0.4 per cent citration is permissible, at least with c t < 30 sec., without significant clot-timing interference.

It is to be emphasized that the significant differences between the activation (and other) data are readily appreciated by simple inspection.

Second phase controls. Whenever any question arises of possible clotting-time modifications due to a reagent having some effect on the *second-phase* (thrombin-fibrinogen interaction), we always run suitable controls, with several thrombins or thrombin dilutions. Examples will be noted in the tables.

TABLE 5—*Stability of Prothrombin in Presence of (Eram) Thromboplastin*

X = 2.0 cc PRO D (0.2%) + 2.0 cc tpln A (0.25%), at room temperature

T = 4 cc X (aged as indicated) + 0.75 cc buffer + 0.25 cc Ca, activated at room temp for periods cited (1 hr). Clotting-times (c t), in seconds for 0.25 cc T + 0.5 cc BF (1%)

N.B. The initial prothrombin solution (in X) had been prepared 6 days previously and stored in ice-box. Unfiltered tpln A was used in T₅.

III. EXPERIMENTAL DATA

"Stability" of prothrombin in solution. The tests of table 4 were made on a 0.2 per cent solution, in borate buffer, of PRO B, which, according to the stated (Seegers) potency of 15,200 thrombin "units" per mg tyrosine N (after activation) is one of the purest preparations. Initial tests, about 2 hours after making the solution, show a trace of active thrombin estimated to be < 0.5 per cent of the total potential thrombin yield, according to c t data in the accompanying *dilution series* (B).

Activation tests (A) were made initially on Oct. 8, 1946, with (T₁) Ca, alone, and (T₂) Ca + tpln A (0.1 per cent). The latter series was repeated (T₂) two

months later, on Dec 9, with another thromboplastin (tpln D), the prothrombin solution having been kept in the ice-box and now showing considerable increase in thrombin content. Nevertheless, it is apparent from the data that there is still much prothrombin requiring activation. Although the activation is much slower in T_1 (Ca, alone), it finally (4 days) reaches a stable optimum of thrombic potency which, as measured by the 3" c t, is identical with that in the other two series. While, therefore, the prothrombin solution is "unstable" in the sense that it slowly changes to thrombin and the more rapidly, the more favorable the conditions for activation, yet it is amazingly stable in the sense of yielding a reproducible amount of thrombin (identical c t) even after two months storage and (ultimately) independent of the mode of activation used.

The absence of *clot-lysis*, or even of *clot-retraction*, in the T_1 series, observed for 10 days at 37 C, is noteworthy. The extremely weak (6 to 7 day) fibrinolysis in the T_2 series confirms other data pointing to a trace of proteolytic enzyme in the thromboplastin preparation. The possible significance of protease contaminants received special attention throughout these studies and the tests for lytic factors will be noted in the majority of the experiments. There is no detectible trace of such factors in PRO B, nor in the bovine fibrinogen (B F).

TABLE 6—*Stability of Prothrombin in Presence of Ca^{++} and Thrombin*

T_{Ca} = 15 cc PRO F (0.35%) + 5 cc buffer + 1 cc $CaCl_2$ (M/10)

A = Activation data on thrombic mixture consisting of 2 cc T_{Ca} (1 min old at start) + 0.25 cc buffer

B = Maximal activation data, selected from series of tests (but always reached within 1 hr) on thrombic mixtures consisting of 2 cc T_{Ca} (age cited) + 0.25 tpln (var fresh preparations)

C t (in seconds), at room temp (23 ± 2 C) 0.5 cc fibrinogen (0.5% B F) + 0.25 cc thrombic mixture

	Time in seconds					
A	250	85	43	25	4	0 (7 day)
B	4	4	4	4	4	3-4 day

Stability of prothrombin during thrombin formation As we shall note more fully in a subsequent section, Seegers' purified prothrombins invariably show a trace of *active* thrombin immediately on making the solution. A great deal more thrombin forms "spontaneously" on standing in solution at room temperature or in the ice-box for several days. The activating factors responsible for this will be brought out in the sequel. In the data (table 4) just considered, it is apparent that this thrombin can coexist in solution with unaltered prothrombin without demonstrable effect on the final thrombin yield. The persistence of unaltered prothrombin, still able to be activated and thus complete the (100 per cent) thrombin yield, after 22 days at room temperature, is recorded in the T_1^* footnote to table 8 A. In the following tables (5 and 6) are data to show that the same is true in the presence of amounts of (a) thromboplastin or (b) calcium salt, that are ordinarily optimal for their respective roles in the activation process.

A Effects of thromboplastin The addition of thromboplastin, alone, is without significant influence on the "spontaneous" activation of purified prothrombin (see table 7, T₂). In the tests of table 5, 0.2 per cent PRO D is mixed with an equal volume of dilute thromboplastin (tpln A, 0.25 per cent) and kept at room temperature for three days. Equal samples were recalcified (a) immediately (20 sec)

and (b) after aging 24, 48, and 72 hours, respectively. At the end of the series, a control (c) was made up to contain the same amounts of prothrombin (now 72 hours older), calcium, and a fresh thromboplastin suspension. The prothrombin activation was followed in the usual way on each of the thrombic mixtures. Except for the minor difference of a slower activation in T₂, T₃, T₄ (probably explained by the thromboplastin in the mixture showing the same sort of deterioration as in ordinary solutions), the thrombin-forming ability is unchanged and results in a

final potency of 3" (c t) in every case. It can be concluded, therefore, that the prothrombin preserves its essential integrity in the presence of the crude brain thromboplastin.

The trace of protease in tpln A (shown by clot-lysis tests of T₂ in table 4) is evidently insufficient for any detectible prothrombinolysis.²

B *Effects of calcium* The addition of optimal amount of calcium salt causes a significant but very minor increase in the slow rate of "spontaneous" thrombin formation and in the purest prothrombins studied full activation may not be obtained even in a week. Table 6 shows such a recalcified prothrombin solution (PRO E), followed over an activation period of eight days. At any intervening period, as the data show, it is merely necessary to add adequate amount of thrombo-

plastin (three different preparations were used on successive days) in order, within less than an hour, to bring the *c t* value to the same stable optimum (4 seconds) in every case. This identical thrombin value is reached on the eighth day in the presence of added Ca, alone. Such reproducibility of thrombin *c t* value is taken to indicate (1) complete (100 per cent) activation of all the prothrombin, and (2) perfect stability of the unaltered prothrombin and of the thrombin which it yields.

*C. Conclusion as to effects of thrombin*¹⁹ From these three experiments, therefore, it is significantly concluded that the presence of thrombin during the intervening period, *i e*, prior to complete activation, shows no demonstrable effects on the unaltered prothrombin, either (a) destructive (*cf*⁵⁰), or (b) as an "autocatalytic"⁷⁹ (?) activator (*cf*¹).

Mechanism of activation of purified prothrombins The data already considered suggest that the "spontaneous" activation of these purified prothrombins depends upon certain trace impurities.⁷⁷ By (a) controlling individual factors discovered to participate in the activation mechanism, and (b) by testing for individual differences in behavior of the several prothrombin preparations, much detailed information can be gathered as to the factors involved.

Experimental study of certain factors in modifying the activation of a partially purified prothrombin Table 7 presents data on certain factors studied in relation to the activation of PRO F, which is a fairly typical representative of Seegers' prothrombin, somewhat aged.

(T₁) shows very slow and incomplete (4 day) "spontaneous" activation, with buffer only, (T₂) shows essentially no effect of thromboplastin, alone (the slight retardation is not very significant), (T₃) shows a minor increase in activation on optimal addition of Ca-salt, alone, although the 4-day *c t* value of 7" denotes only about 20 per cent of complete activation (according to the thrombin dilution series B), (T₄) shows rapid (< 1 hour) and complete activation by Ca + tpln A (0.25 per cent).

Pancreatic trypsin (tryp), in a final concentration (chosen in an effort to minimize interfering proteolytic effects) of 4 "units" per cc of thrombic mixture, is an excellent activator, especially in the presence of Ca (T₅). In this experiment (*cf* fig 3), trypsin was also very effective when used alone (T₆) or with thromboplastin (T₇), *i e*, without added Ca. T₇ and T₆ are almost identical.

The lengthening of the clotting-times after the optimum, in these three series, is due to a *thrombolytic* action of the trypsin. Even the 1"-2" difference between the optima (as compared with the 3" *c t* optimum of T₃) may be significant of some *prothrombinolysis*. Speeding up of *fibrinolysis* by a day, in T₆, is significant, and the 3-day clot-lysis in T₆ and T₇ even more so (*cf* T₁ and T₂).

Streptokinase (strep) was included in these experiments (T₈, T₉, T₁₀) in order to control later tests (table 13) in which this agent was to be used as an activator of tryptogen (protease precursor) in certain plasma materials.³³

Tests show only minor effects which can be explained in two ways, *viz* (1) some calcium content of the strep preparation, (2) some speeding up of the second-phase of the clotting process. The latter is shown in the control tests C. It is an example of the nonspecific effect of many adsorptive colloids, the action of which we refer to as *fibrinoplastic*.¹⁸ In the absence of thrombin, the streptokinase has no

coagulant properties (C, O) Neither does it show proteolytic effects (T_9 , T_{10}) but, if anything (T_8), lessens the effectiveness of the fibrinolytic factor noted in T_3

Before going on to a detailed consideration of the individual prothrombin-activators, we shall present some data on the effects of certain *inhibitors* because of the light they shed upon the activator mechanisms

Effects of certain inhibitors on activation of purified prothrombin

(Tables 8 and 9) *Citrate* (citr) The 'spontaneous' activation of these prothrombin solutions is very greatly inhibited by 4 mg per cc (final concentration) of trisodium citrate. Only after a week is there evidence of a trace of activation, but this is still barely noteworthy at the end of two weeks, and only 1 per cent (approximate) in three weeks (table 8, T_2). The persistence of unaltered prothrombin, on the twenty-second day, is shown by incubating the residual T_1 , T_2^* with Ca +

TABLE 9 — *Inhibitory Effects of Heparin During Prothrombin Activation*

T_1 = 4 cc PRO E (0.35%) + 0.5 cc buffer soln + 0.25 cc tpln A (0.25%) + 0.25 cc M/10 CaCl_2

T_2 = 4 cc PRO E (0.35%) + 0.5 cc hep (100 unit) + 0.25 tpln A (0.25%) + 0.25 cc M/10 CaCl_2

Clotting tests 1a — 0.25 T_1 + 0.25 buffer soln + 0.5 B F (1%)

3 (with trypsin)*	32"	—	8"	5"	4"	4"	8"	14"	40"	—

tpln for 1 hour T_1 is brought to the 'complete' c t of 4 seconds T_2 fell only to 44 seconds and proved unstable (48 seconds in 4 hours), but the obvious growth of a *mold* in the solution could explain the lysis of prothrombin (and thrombin). In a very similar but unspoiled test, T_1 of table 16, the citrated PRO G was brought to the full c t 4 seconds value, on the seventeenth day (v p 1149). The citrated prothrombin, from the start, shows a faint trace of coagulant activity, which is the best evidence that the prothrombin actually contains this as a trace impurity and not as the result of activation proceeding only in solution.

Crystalline pancreatic trypsin inhibitor^{22 52} (T_1) table 8, T_4 , shows that 0.2 mg per cc (final concentration) of crystalline pancreatic trypsin-inhibitor is almost without effect on the activation of prothrombin by Ca-alone, while 0.5 mg per cc has only a slight delaying action on the activation by Ca + tpln.

(The enzyme-inhibitor does delay clot-lysis by about a day (37 C).)

*Crystalline soybean trypsin-inhibitor*¹⁴ (S B I) in final concentration of 0.2 mg per cc, is markedly inhibitory to the activation of prothrombin both by Ca-alone (T₆) and by Ca + tpls (T₈). Its inhibition of the fibrinolytic enzyme is complete.

The differences between S B I and T I may be significant, suggesting that the soybean inhibitor has certain direct "antithromboplastic" (? anticephalin) effects not seen (to any important extent) with T I and probably unrelated to its effects on any protease present.

The *second phase effects* of citrate and the trypsin-inhibitors are negligible in the control tests (table 8, C).

*Heparin*³¹ (Hep) It is important to note Seegers' claim⁶¹ that his purified prothrombins are 'antithrombin'-free, and there is no reason, therefore, to suspect that heparin, as used in the tests of table 9, is acting other than directly, i.e., in the absence of 'co-factor' or 'heparin-complement'. In the amount used (100 units, = 1 mg per cc), heparin has some "antithrombic" inhibitory (clot-de-

TABLE 10—Effects of Varying Amounts of Ca⁺⁺ During Prothrombin Activation

laying) effect on the *second-phase*, which can be seen by comparing series 1b (in which heparin was added to the fibrinogen in amounts exactly corresponding to those entering the clotting mixtures in series 2 with the heparin-free mixtures of series 1a. It is noteworthy that this antithrombic action is most marked in the case of the weak initial thrombins but almost negligible (½ second) in the powerful fully-formed thrombins at the end of the series. Series 1b, therefore, is the proper control for the *first-phase* action of heparin, which series 2 shows to consist in a marked delaying ("antiprothrombic," in a general sense)¹⁸ action on the prothrombin activation. After a week, however, the 4½ seconds c t is identical with the control, proving that there is no difference in the ultimate thrombin yield. These results closely resemble those obtained¹³ by a slight reduction of the thromboplastic factor (table 11) and are best termed 'antithromboplastic'¹⁷ (cf ⁵).

(From data published elsewhere,³³ it is established that heparin, acting alone, is unable to inhibit the fibrinolytic enzyme.)

Consideration of individual prothrombin-activators

I CALCIUM

The ability (a) of citrate (or oxalate, etc.) to prevent the 'spontaneous' activation of prothrombin solutions and (b) of added *ionized* Ca-salt to speed up thrombin formation, to a degree depending upon certain "thromboplastic" factors (see below) confirms the long-established fact¹¹ that ionized calcium (Ca^{++}) is ordinarily essential for the activation of prothrombin to thrombin

Amount of calcium present Paucity of materials precluded any attempt at quantitative Ca analysis of these prothrombins, particularly since the inability to improve the extremely slow "spontaneous" activation by simply adding thromboplastin (e g table 7, T₂) was believed to indicate that very little calcium could be present. However, a qualitative test, in which 1 cc of 0.4 per cent PRO G was treated with an equal volume of M/1 $\text{K}_2\text{C}_2\text{O}_4$, showed a definite turbidity and overnight sedimentation of a trace of calcium oxalate. In this particular preparation,

TABLE 11—Effects of Varying Thromboplastin Concentration on Activation of Prothrombin, with Special Reference to Thrombin Yield

5 cc vol of (T) thrombic mixtures (A-E) containing 2 cc PRO A + 0.25 M/10 CaCl_2 + tpn A (final dilutions stated), in borate buffer (pH = 7.7) C t (sec), at room temp ($25 \pm 2^\circ \text{C}$) 0.5 B F (1%) + 0.25 T

CLOT-LYSIS (at 37 C)	3 day	5 day	>7 day*	0 (7 day)	0 (7 day)

* Good clot-retraction, but lysis incomplete

therefore, contamination with some available calcium was actually demonstrated. PRO G was used in the experiments of table 7, but neither in this case nor in the data of similar studies (see tables) can the test with buffer alone be taken as evidence of differences in the amount of calcium operating (as compared with the recalcified mixtures), since the thromboplastic factor is also a variable. Only when thromboplastin, alone, is added, as in T₂ of table 7, without improving the activation, can it be suggested that inadequate amount of available calcium (in PRO F, in this case) is responsible for the extremely slow and inadequate thrombin formation. It is not possible in the 4 day observation period of this particular experiment to predict the ultimate thrombin yields in T₁ and T₂. The mode of action of 'thromboplastic enzyme' is discussed later (pp 1146, 1150) but it may be stated from the data of table 7 that *trypsin* appears able to make both calcium and thromboplastic factor (prob cephalin) available' from otherwise inert combinations with the prothrombin protein (T₅, T₆, T₇)

Effects of varying Ca^{++} concentration in first phase of clotting (Table 10) It has long been recognized¹¹ that the essential action of Ca-ions in the clotting process is

limited to the first phase (activation of prothrombin) and requires a Ca^{++} concentration above a certain "minimum" and not in excess of a certain "optimum" because of inhibitory effects¹⁴⁻¹⁷ The exact working out of the effects of varying the amount of calcium during first phase tests is rendered difficult⁷⁰ because of a significant second phase action, at least with higher Ca concentrations, due to relatively nonspecific ion effects during the thrombin-fibrinogen interaction⁶⁸ The experiments summarized in table 10 represent a new attempt to clarify this problem

All reagents, including CaCl_2 , were dissolved in borate buffer The (added) Ca content was varied from 0.005M (T_1 - T_5) and the amount of thromboplastin was kept constant throughout A series of *diluents* was prepared containing the same amount of thromboplastin and exactly enough CaCl_2 for admixture with an equal volume (0.25 cc) of the respective thrombic mixtures and 0.5 cc B F to

FIG. 2. EFFECTS OF OXALATE AT VARIOUS STAGES (ZONES) OF PROTHROMBIN ACTIVATION (ref Am J Med 3 67, 1947) Clotting- and incubation-times at 25°C, pH = 7.7 (borate buffer)

I Thrombic mixture (T_1) 13.5 cc PRO C (0.5%) 0.75 cc tpln A (0.25%) + 0.75 cc M/10 CaCl_2 Clotting tests 1 cc B F (1%) + 0.25 cc buff 0.25 cc T_1 II Clotting tests 1 cc B F (1%) + 0.25 cc M/1 $\text{K}_2\text{C}_2\text{O}_4$ + 0.25 cc T_1 III Thrombic mixture (T_2) 3 cc T_1 (5 min old) + 3 cc M/1 $\text{K}_2\text{C}_2\text{O}_4$ Clotting tests 1 cc B F (1%) + 0.5 cc T_2 IV Thrombic mixture (T_3) 3 cc T_1 (30 min old) + 3 cc M/1 $\text{K}_2\text{C}_2\text{O}_4$ Clotting tests 1 cc B F (1%) + 0.5 cc T_3

bring the Ca concentration in the final clotting mixture to 0.0125M in every test The control of Ca and tpln in the "second phase" is, therefore, complete The optimal 4 seconds c t was identical in T_2 - T_4 and no difference was noted in another test, not included in the table, with T_3 + buffer (instead of diluent) which reduced the Ca concentration to 0.00125M Thus, in a range of Ca concentration without second phase effects, there is seen (table 10) marked variations in the rate of prothrombin activation, but no effect on the amount (potency) of thrombin ultimately formed For this 'first phase' action of Ca salt, there is a definite optimum at about 0.005M (T_3), with delayed activation below this (T_2), and an inhibitory slowing at higher Ca^{++} concentrations (T_6)

Effects of oxalate (or citrate) during prothrombin activation The thrombin- intermediary " In 1937 we published some experiments in support of the view that

thrombin formation proceeds via an intermediary" (calcium-prothrombin-cephalin) complex or compound¹² Although this idea seems to have been well received (ref⁷⁰), the intervening decade has not brought forth confirmatory publications from other laboratories. We have, therefore, taken the present opportunity to repeat the same kind of experiments with the newer highly purified prothrombins. Fig. 2, reproduced from a recent review,²⁹ shows what we believe to be a typical result. In this experiment, a control (1) thrombic mixture (PRO C (0.5 per cent) + Ca + tpin) was followed without oxalate. A portion of the same mixture was removed (a) after 5 minutes (3) and again (b) after 30 minutes (4), in each case being added to an equal volume of M/1 $K_2C_2O_4$ and the further activation studied, by using *double the volume* of the new mixture in the clotting-test. A second-phase control (2) consisted in adding, to the fibrinogen, a *single volume* of the original thrombic mixture shortly (60 sec.) after the addition of a like volume of M/1 $K_2C_2O_4$. Buffer was used instead of oxalate in 1.

Under these fully-controlled conditions, therefore, it is highly significant that the earlier (5 min.) oxalation (3) of the prothrombin-thrombin mixture showed *progressive loss* of thrombic potency, in marked contrast to the "riper" (30 min.) mixture (4), which is unaffected by addition of oxalate. Our earlier paper¹² may be consulted for evidence that the final thrombin may be "decalcified" by oxalation and electrodialysis without significant loss of thrombic potency.

II THROMBOPLASTIC PHOSPHOLIPID

A *Cephalin* (ceph.) The phosphatide, or more accurately the group of phospholipids (since there are isomers and homologues with varying fatty acid radicals, not all of which are clot-aiding¹⁴), designated chemically as *phosphatidyl ethanolamine*,³⁵ is a 'thromboplastic' agent. At least this is true of the P-lipid as isolated from brain and other tissues as well as from plasma, etc., the fact being first clearly recognized by Howell³⁹ and Zak⁷¹ in 1912, although the identification of the phosphatide required later work and may still be incomplete.¹⁻⁴ In some earlier quantitative studies¹⁴ on crude (Howell-type) prothrombin, we showed (1) as little as one part of cephalin in several millions has distinct thromboplastic effects, (2) thrombin yield depends upon amount of 'free' (or 'available') cephalin present, (3) considerable amounts of cephalin (and other substances) can be demonstrated in combination with the prothrombin protein¹⁰ even when it shows little, if any, ability to be activated by Ca, alone.³⁰

It would be highly desirable to repeat these data, especially (a) the analytical and (b) the full study of thrombin yields, upon the newer prothrombin preparations. At present, however, we are handicapped by lack of cephalin and of sufficient prothrombin. With two old (several years) and weak cephalin preparations, we were able to confirm the thromboplastic action of the P-lipid, but this is the extent of the data which, for the present, we can include under this head.

B *Thromboplastin* (tpin) We have had no opportunity to study the *thromboplastic lipoprotein* which Chargaff et al.⁴ claim to have isolated from lung tissue and plasma. The present data were obtained with the use of various crude *thromboplastin* (*thromboknase*) preparations described under *Reagents*. Mertz, Seegers and

Smith⁵⁰ found that the amount of added thromboplastin (a lung preparation) determined the thrombin yield from purified prothrombin. Table 11 shows the essential data when we follow for 7 days the effects of varying concentration of brain thromboplastin (tpln A) added to recalcified dog prothrombin (PRO A), a partially purified preparation. The least amount of the tpln in the thrombic mixture was 1:400,000 which was weak, but by no means minimal. The 1:1000 and 1:500 concentrations are clearly maximal. Owing to the limited amount of prothrombin available, there was insufficient thrombin for a dilution series, but it is clear, nevertheless, that (1) above a certain "maximum," increasing the thromboplastin concentration speeds up the *rate* of prothrombin activation without increasing the thrombin *yield* (as shown by c t value), whereas (2) below a certain "optimum," lessening the thromboplastin definitely reduces the final amount of thrombin formed, in addition to greatly slowing the rate of activation. Thus, the main facts, previously reported with regard to the thromboplastic action, whether of cephalin¹⁴ or crude thromboplastin,⁵⁰ are adequately confirmed in the present study.

The data of table 11 again clearly show the trace of fibrinolytic factor, which, since it diminishes with the thromboplastin concentration, must come chiefly from this source.

Deterioration of thromboplastic impurity in prothrombin preparations. During the course of these investigations we had occasion to secure prothrombin activation data of similar kind on repeated experiments with the same prothrombin preparation over some weeks or months. It became apparent that a change in the character of the activation could often be noted. An especially good example of this is seen in data obtained, as little as three weeks apart, in the case of PRO G, as is clearly seen from the data collected in table 12. The rate and degree of "spontaneous" activation are particularly affected (1a vs 1b), but there is also much weakening of the ability to be activated by Ca, alone (2a, 2b). Even the better start which the Ca gets in a repetition (2c) of the last test, after 24 hr. keeping the PRO G solution (in ice-box), does not significantly hasten completion of thrombin formation. However, there is no appreciable difference in the response to Ca + tpln (3a, 3b), which is complete (4 seconds c t) in one-fourth to one-half hour in both instances, thus proving that the properties of the prothrombin itself are stable. The lengthening of the clot-lysis time by about one-half day in 2b, 3b hardly seems significant. The conclusion favors the idea of a deterioration of a more essential thromboplastic factor than the protease impurity. Our guess is that this refers to the thromboplastic phospholipid ('cephalin-like' in character).*

III THROMBOPLASTIC ENZYME

Thromboplastic enzyme in relation to blood-clotting and proteolytic phenomena

The Ferguson blood-clotting theory²³ centers around a special thromboplastic role of small amounts of natural plasma or tissue proteolytic enzyme (tryptase⁵³ or

* It is possible that we were here encountering the effects of an unstable accessory factor "called *accelerator globulin* by Ware, Seegers et al. (see Addendum).

*plasmin*⁶ or fibrinolytic protease¹²) However, this is not regarded as a basic factor, since prothrombin, in our experimental systems, is rapidly and completely converted into thrombin by calcium (Ca^{++}) and cephalin (thromboplastic phospholipid) even when no protease can be demonstrated We had shown this previously³⁰ when using crude prothrombin Trypsin, *in vitro*, corrects the thromboplastic defect of hemophilia¹⁶ In the present study, all the thromboplastic preparations (except cephalin) showed at least a trace of tryptase impurity, revealed by the clot-lysis test The role of the thromboplastic enzyme we believe to be of the nature of a weak digestive action ("disaggregation," Pope⁵⁷) upon the complex unions of plasma proteins with phospholipid and calcium, thereby *mobilizing* or making "available" these necessary activators and thus, in a sense, 'catalyzing' the prothrombin activation The high fidelity with which the new purified prothrombins permit us to follow the course of the activation process has enabled us to contribute the following highly significant data on (1) the thromboplastic activity of natural tryptase in a variety of plasma products and (2) certain interrelationships between thromboplastic and proteolytic properties Highlights of these data are (3) use of streptokinase (*infra*), instead of the less reliable Delezenne and Pozerski⁶⁶ (1903) 'chloroform-method,' for activation of protease precursor (tryptogen) and (4) study of effects of certain recently isolated crystalline trypsin-inhibitors, of protein or polypeptide nature, from pancreas⁵² (T I) and soybean⁴⁴ (S B I)—see *Reagents*

Thromboplastic action of tryptase (streptokinase-activated tryptogen) in human, and other, fibrinogen-containing plasma fractions Our first clear demonstration of the 'thromboplastic action' of natural plasma tryptase was made with streptokinase-activated human plasma Fraction-I (H F) and the more refined fibrinogen (H Fb) obtained from the Harvard laboratories (see *Reagents*) The data of table 13 are reproduced, with minor modifications (including clot-lysis data), from *Proc Soc Exper Biol & Med* 64 312, 1947³⁴

The preliminary *fibrinogenolytic tests* (A) show that streptokinase (strep) activates the plasma tryptogen, in H F, to a proteolytic potency comparable to that of 20-unit (final concentration = 2 units per cc) trypsin (tryp)—(see *Reagents*)

The thrombic mixtures for the activation tests (B) consist of 5 cc vol, containing 2 cc PRO B (protease-free-*vs* T₁), 2.5 cc of lysate (or buffer) + 0.25 cc buffer + 0.25 cc Ca Thus, the trypsin concentration (final) in T₄ is only 1 unit (= 0.01 mg) per cc Obviously, the amount of protease in these activation tests is very small indeed

The activation data, in the presence of optimal calcium (added in all tests), clearly show the 'thromboplastic' improvement in thrombin formation by the *lysates* A (tryptase) and B (trypsin) in T₃, T₄, respectively Heat-defibrinated H F (C) is used to control the possibility of some thromboplastic factor, other than the proteolytic agent, being the cause of the T₃ result The series T₂ is practically identical with series T₁ (Ca only) Thus, we conclude, the enzyme acts in conjunction with the trace of thromboplastin mobilized from the prothrombin preparation

We have previously noted (table 7) that the *streptokinase* (protease activator) is devoid of significant thromboplastic, thrombic, or proteolytic effects

Other data on streptokinase-activated human fibrinogen (H Fb), dog $(\text{NH}_4)_2\text{SO}_4$ -pptd fibrinogen (D fb)—see *Reagents*—are essentially similar

Thromboplastic (and thrombic) actions of III-3 and effects of trypsin-inhibitors (see *Reagents*) Table 14, modified (by inclusion of (1) thrombin 'percentages' and (2) clot-lysis tests) from data in the above-cited publication,³¹ shows a definite 'thromboplastic' action of the protease contained in the Harvard human plasma fraction III-3^{3a}

The c t data of the thrombin dilution series, in section B, enable us to express the degree of activation in relative thrombin 'percentages' (v p 1134) Those for the 1 hr incubation are included in section A Note

1 The 100 per cent activation by Ca + tpls (T₁) was actually obtained in $\frac{1}{2}$ hr and remained stable for a week or more

2 Ca, alone (T₂), gave only 1 per cent, in 1 hr

3 Ca + enzyme (T₃), increased this to 25 per cent, a considerable "thromboplastic" effect

4 III-3 is not an ideal tryptase preparation, because it has some "thrombic action" of its own, but the control (T₆) shows this to be only 1 per cent, quite unable, therefore, to account for the above effect

5 Pancreatic trypsin-inhibitor (T₄) reduces the thrombin formation to 10 per cent

6 Soybean trypsin-inhibitor (T₅) diminishes it to less than 1 per cent, completing inhibiting the thromboplastic enzyme The question of an additional direct "antithromboplastic" action of S B I was raised on p 1142 (and see table 8) and is fully answered below

Nomenclature Our nomenclature^{27a} of the fibrinolytic and thromboplastic plasma protease as tryptase (cf⁶⁹) is tentative and based on the practical consideration of many similarities (despite differences in origin, etc.) to pancreatic trypsin There is no current agreement on nomenclature,^{9a} however and there are certainly several plasma proteases, e g, cathepsins,⁴³ and possibly papain like enzyme The coincidence of thrombic and proteolytic actions in III-3 might suggest a papainase (cf⁴³), were it not for the fact that our other tryptase preparations lack the coagulant effect

Modes of action of trypsin-inhibitors

1 *Antitryptic effect* These known pancreatic-trypsin inhibitors were shown to inhibit plasma tryptase in fibrinogenolytic and fibrinolytic tests³³

2 *Antithromboplastic effect* The later tests of T₅ series (table 14) suggest that S B I antagonizes not only the protease but also the natural thromboplastic (phospholipid) factor which continues to operate in the control (T₁) There is no good evidence for this in the case of T₁ The control tests (without added enzyme) in table 8, were made with the same prothrombin (PRO G) as the table 14 series They clearly show inhibition of prothrombin activation by S B I, both (T₅) with Ca, alone, and, more significantly (T₈), with Ca + tpls The T₁ shows negligible effects of this sort

It is concluded, therefore, that the soybean- (not the pancreatic-) trypsin-inhibitor has additional direct antithromboplastic (? anticephalin) effects, somewhat like the first-phase action of heparin (table 9)

3 *Second-phase controls* The negligible effects of trypsin-inhibitors in the second-phase are proved in the data of table 8, C An additional possibility that S B I (under certain circumstances) might serve as a co-factor for the antithrombic effects of heparin was also ruled out by some tests noted in table 15 Observe the slight immediate antithrombic effect of 25 Toronto units per cc (final concentration) of heparin on the thrombin (0.5 per cent h g) tested (in which there is no reason to suspect the presence of any co-factor) The S B I had no antithrombic action (a) immediately or (b) after 1 hr, whether tested alone or with heparin

Other active tryptase preparations None of the other plasma fractions studied, except the less purified *prothrombins* G and A (see table 1) and some commercial *thrombins* (e g table 20, TL₆) showed coagulant activity as well as protease effects. Protease could not be detected (table 18) in the highly purified prothrombins (B—E), nor in certain thrombin preparations (table 20, TL₄). It is certain, therefore, that it must be regarded as an impurity. Excepting cephalin (purified P-lipid), all the *thromboplastic agents* (see *Reagents*) tested were found to contain a trace of tryptase (cf ⁴⁰). In view of this ubiquity of tryptase in all but the most highly purified plasma and tissue products, it is not surprising that we were able to demonstrate both the lytic and thromboplastic (weak) effects of this protease in crystalline *serum albumin* preparations (Harvard Laboratory^{3a}—see *Reagents*) of both human (H S A) and bovine (B S A) origin.

Dog plasma tryptase Our current preparations of high-potency plasma tryptase are not yet perfected (see *Reagents*), but the preliminary data are confirmatory of those on other tryptase preparations, with a few important additions.

Table 16 shows some prothrombin (PRO G) activation data, using dog plasma tryptase (trypt D), with and without trypsin-inhibitor and other activators.

In T₂, 1500 tryptase slightly improves the weak clotting in citrate (cf T₁), but the most significant point is the virtual absence of activation in 1 to 2 days, in both series. The 95 per cent (approximately) unactivated prothrombin, at the end of a 17-day period, was completely converted, to 4 seconds c t, after 1 hr incubation with Ca + tpln D (see Footnote,* table 16, A) (Fibrinolysis was advanced but not quite complete in T₂ series on the 7th day (37°C), whereas the control (T₁) series were negative).

The thromboplastic action of the tryptase is seen in T₄ and T₅, as compared with the T₃ control (Ca, only). When thromboplastin plus Ca are the activators (T₉), the tryptase is hardly necessary, but it does reduce the total activation time from 2 to 1 hr (T₁₀).

The fibrinolytic potency of the added trypsin is marked in T_5 and evident in T_4 (by completion of lysis in 1 day less than in T_3). The same is true of T_{10} versus T_9 .

Two reasons are suggested for the failure of the thromboplastic action to be as strikingly evident as the fibrinolytic effect (1) Deterioration of thromboplastic (? P-lipid) impurity, as previously noted (table 12), (2) Prothrombinolysis, in case of stronger protease T_6 , as shown by the longer early c t values, together with some thrombinolysis, definitely shown in the late c t values. The failure to reach

less than a 13 second c t is especially significant. With the weaker trypsin, however, the first of these two reasons must be invoked. The similarity to the trypsin data of figure 3, in the section to follow, is noteworthy.

Mode of action of thromboplastic enzyme. We have already (p 1146) mentioned our theory that trypsin (experimentally) or tryptase (naturally) are only accessory to the basic mechanisms of prothrombin activation by calcium ions and thromboplastic phospholipid (cephalin). Tryptase, therefore, can be expected to work only in the presence of adequate amounts of the true activators. In the original presentation of the thromboplastic enzyme theory,²³ it was commented that the final answer must await the preparation of prothrombin entirely free from all traces of its ac-

tivators This difficult goal is, obviously, not fully achieved by Seegers' methods of purification Nevertheless, some highly significant facts emerge from a critical consideration of certain differences in behavior of individual prothrombin preparations, particularly when the preparations act in the presence of thromboplastic enzyme

Limitations of thromboplastic action of trypsin The differences between the data of figure 3 and table 17 are especially interesting

A Data for figure 3 were obtained on an old prothrombin preparation (PRO C) Thrombin 'percentages' (100 per cent = complete activation) were obtained from a thrombin dilution series, plotted as $1000 - ct$ (sec) in the dotted line, and used to construct the 'activation curves' I-IV The 5 cc volume thrombic mixtures all contained 4 cc PRO C (0.3 per cent) + 0.25 cc M/10 CaCl_2 , with the following additions (I) 0.75 cc buffer only, (II) 0.25 cc buffer + 0.5 cc trypsin (40-unit/cc), (III) 0.5 cc buffer + 0.25 cc tpln A (0.25 per cent), (IV) 0.25 cc tpln + 0.5 cc trypsin Note the results (I) Ca (alone) produces slow activation complete in 50 hours, (II) Ca + trypt is not significantly better, (III) Ca + tpln is adequate but rather slow in the later stages, thus extending the complete activation to about 24 hrs, (IV) Ca + tpln + trypt is significantly best and completes over 90 per cent of the activation in less than 1 hour, although, here again, the penultimate stages are still rather slow and require up to 16 or 18 hours for 100 per cent completion

Clot-lysis was followed for 4 days, only, in which time it was absent in I, incomplete in III, and complete (24-48 hours) in II and IV Other tests failed to show any protease in PRO C (table 18)

B Table 17 also gives 'percentage' data, computed from a thrombin dilution series It gives a very good idea of the progress of the activation, under various activator conditions Omitted from the table are (1) *Control tests*, with Ca + tpln, which show the fibrinogen to be prothrombin- (and thrombin-) free, (2) Tests with PRO D and (a) buffer only and (b) + tpln only, which show only negligible traces of thrombin already present in the prothrombin solution (Weak as they were, these traces of clot resisted fibrinolysis for a week at 37 C)

Note the following results, in sharp contrast to those of PRO C (fig 3) (T_1) a stronger tpln + Ca gave complete (100 per cent) activation in $\frac{1}{2}$ hr, while (T_2), a weaker tpln + Ca needs 48 hrs This is reduced by 4-u of trypsin to only 3 hrs, but (T_5) trypt + Ca (without added tpln) is nearly as good, except in the earlier stages, (T_4) Ca, alone, is slower to start than Ca + tpln (T_2) but is complete in the same length of time (48 hrs) (T_6) Trypsin, alone, produces maximal activation in 6 hours, but this amounts to only 20 per cent of the potential activity, and even this rapidly falls off in the next 24 hrs Loss of thrombic potency after maximal activation is also seen in T_3 and T_5 Clearly, the trypsin has prothrombinolytic and thrombinolytic powers

Clot-lysis fails to reveal any trypase in the prothrombin (T_4) but there is evidently a trace in tpln C (T_7) The tryptic fibrinolysis is readily detected (T_3 , T_5 , T_6)

The *activation tests* (with "trypase") in tables 13 and 14 resemble those of table 17, while the data in table 16 are suggestive of those in figure 3. The significant differences in enzyme (protease) effects incidentally noted in a large, but not always complete, set of studies on PRO'S A, B, C, D, E, F, and G, are collected in table 18. Without entering into a detailed analysis of the data it can be concluded, with considerable probability, that the differences consist in the varying amount of (a) thromboplastic phospholipid factor, and (b) calcium (especially note T_1 table 7 *versus* T_2 table 16) "available" (1) immediately or (2) because of the actions of the proteolytic enzyme, for the prothrombin-activation. Lack of trypase is a simple explanation of the unduly long incubation period necessary for $Ca + tpln$ to activate highly purified prothrombins, if it can be assumed that the ac-

FIG 3 EFFECTS OF TRYPSIN ON THROMBIN FORMATION, FROM PURIFIED PROTHROMBIN *apparently* CONTAINING INSUFFICIENT TRACE OF THROMBOPLASTIN (ref Ann N Y Acad Sci 49 486, 1948)

Experimental data given in text. Thrombin formation at successive incubation times (t) computed from inverse clotting times ($1000 - t$ (sec)) of thrombin (III) dilution series (dotted line) for the following mixtures I PRO C + Ca, II PRO C + Ca + tryp, III PRO C + Ca + $tpln$ A, IV PRO C + Ca + $tpln$ A + tryp. 25 C, pH 7.7

celerator globulin (see Addendum) is adequate. The data are all very clear in terms of the thermoboplastic enzyme theory.

Suggested scheme for routine testing for "trace impurities" in prothrombin preparations
The foregoing experimental analysis of the activation mechanisms suggests four simple routine tests which should be made on all prothrombin preparations.

A 0.5 per cent prothrombin solution in our borate buffer (see *Reagents*) is recommended, with the addition of 0.4 per cent (final concentration) of trisodium citrate (except in IV). Thrombic mixtures (T) 5 cc vol, containing 2.5 cc PRO (0.5 per cent) + activators, as follows (*v. infra*). Clotting-tests, at room temperature, on 0.5 cc prothrombin- and enzyme-free fibrinogen (e.g. 0.5 or 0.25 per cent BF, the "half-strength" being recommended for protease tests, I).

I. *Test for protease* (trypase), by clot-lysis at 37 C. T_1 is activated by 0.25 cc M/10 $CaCl_2$ for suitable periods (e.g., 1, 4, 24, 48 hrs), timing the clotting (at room temperature) and then incubating (37 C) for fibrinolysis. If a suitable *enzyme free* thromboplastin (e.g., 1:1000 cephalin) is available, it would greatly shorten the necessary incubation. Owing to trypase contaminants commercial thrombo-

plastin preparations are usually unsuitable. The protease may be assayed in "fibrinolytic" units by our "method A" (p 1156)²¹ using standard trypsin dilutions (1 mgm — 100 units) and an enzyme-free thrombin (e g 1 per cent h g — see *Reagents*) to clot the fibrinogen.

By this test, significantly, all Seegers' highly purified prothrombins, except PRO F, (table 18) are quite free from tryptase. This is definitely not the case, however, with (a) partially purified prothrombins (G, A), nor (b) with most of the currently available *thrombin* preparations (table 20).

TABLE 14 — *Thromboplastic Action of Plasma Trypsin II Human Plasma Fraction III-3 (Harvard)*
Effects of Trypsin-Inhibitors

A Prothrombin activation data

C t (sec), at 24 C, pH = 7.7 (borate buff) 0.5 cc BF (0.5%) + 0.25 cc T

T 5 cc vol, containing 2 cc PRO G (0.4%), 0.25 cc M/10 CaCl₂, 2 cc III-3 (0.1%), 0.25 cc tpls B (0.75%), 0.75 cc trypsin-inhibitor (from pancreas T I, 0.2%, from soybean, S B I, 0.2%), where indicated

T	Activators	Inhibitor	$\frac{1}{4}$ m	$\frac{1}{4}$ hr	$\frac{1}{2}$ hr	1 hr	%, 1 hr	1 dy	7 dy	Clot lysis (37C)
			seconds					(seconds)

C t (sec), at 24 C 0.5 cc BF (0.5%) + 0.25 cc T₁ (3 day old), dilutions stated

Rel T conc %	100	50	25	10	5	1	0.5
Clotting-time, in seconds	4	8	11	22	41	84	127

II *Test for thrombin* Provided that the prothrombin is free from protease (or, possibly, by ensuring this by the addition (with controls) of a little trypsin-inhibitor), the addition to 0.5 cc of the test fibrinogen of 0.25 cc of *citrated* PRO is at least a qualitative test for the presence of even very minute traces of thrombin.

III *Test for thromboplastic factor* (? cephalin, ?? lipoprotein) Test I gives some indication of the immediately available thromboplastic factor, but supplementing T₁ with 0.5 cc of 20-unit/cc *trypsin* (see *Reagents*) before the clot-timing (T₂, 0.25 cc + BF, 0.5 cc, at room temperature) test series will greatly speed up the activation (to minutes or an hour or two, instead of days) if 'available' thromboplastic factor is present. On the other hand, deficiency of this factor will be shown by the lack of difference between III and I (Ca-alone), control.

IV *Test for available calcium* This must be made in the absence of 'decalcifying'

anticoagulant "Spontaneous" activation and especially the acceleration of this by added thromboplastin (alone) is indicative of "available" calcium. The most rapid and satisfactory test, however, is to use (T₁) a thrombic mixture containing PRO

TABLE 15—*Lack of Antithrombic (second-phase) Effects of Crystalline Soybean Trypsin Inhibitor, with and without Heparin*

Ct (sec) for 0.5 BF (0.5%) + 0.5 thrombic mixtures (I-IV), consisting of 0.25 cc hg (0.5%) + 0.125 cc, each, of inhibitors noted. Tests made immediately (15 sec) and repeated after thrombic mixtures had stood at room temp (22 C) for 1 hr.

* Protease in prothrombin (recalcified) tested b, time required for complete clot lysis

† Uncontrolled test, at 39 C

is ruled out in nearly all the highly purified products (table 18) studied, but is shown in those that are only partially purified (esp G, A). We are not yet fully able to account for the fact that the protease impurity always shows up best in *recalcified* thrombic mixtures. McDonald and Kunitz⁴⁹ have shown the importance

of calcium in the formation of trypsin from crystallized trypsinogen (pancreatic) but our experiments, to date, have not definitely proved whether this kind of action is involved in the plasma tryptase system

Clot-retraction is evidently a preliminary stage of fibrinolysis in our in vitro tests, where it is not at all uncommon to observe a very weak protease cause retraction of the clot without complete fibrinolysis (e g, T_C , table 11) In ordinary blood clot retraction, platelets and other cellular elements⁵³ may very well contribute proteolytic enzyme(s)²⁵ We have found tryptase in platelets by means of the fibrinogenolytic test It is not improbable that colloidal syneresis, of the nature of elastic retraction due to micellar rearrangement, may also be involved in clot retraction, but a partial fibrinolysis could be an essential initiating force

In a somewhat analogous manner, a colloidal phenomenon (coacervation, Mommaerts⁵¹), characterized by interlacing of the elongated (filamentous) fibrinogen molecules and micelles, may be the funda

* Alternate tubes tested at the respective temperatures

mental explanation of their aggregation to form fibrin, but, here again, a specific causative agent is necessary, and this is the function of thrombin Thrombin is not proteolytic (v supra) but the proteolytic enzyme papain (see p 1148), which can also produce true fibrin, also has fibrinolytic powers⁴¹

II *Fibrinogenolysis* As we have previously shown, lysis of fibrinogen,²⁰ even better than fibrinolysis,²¹⁻²⁴ is an excellent quantitative method for assaying trypsin-like enzymes, with a sensitivity of the order of 1:1,000,000 The two tests, which we term 'method B' and 'method A,' respectively, may be adapted for the study of natural proteases related to the blood-clotting system, which study is being further prosecuted in our laboratories *

It is significant that small amounts of contaminating plasma proteases do not greatly interfere with the clotting-system In part this may be due to the wide range of fibrinogen concentrations that give optimal clotting (table 2) In certain situations, however, such as the noncoagulability of cadaver⁶⁴ and menstrual blood,⁴⁸⁻⁶⁵ a simple explanation is forthcoming on the basis of the fibrinogenolytic action of larger amounts of tryptase, *with* or *without* thrombic clotting

* More recent experiments emphasize practical difficulties due to differences in the shape of the lysis curves (plotted against incubation time)

III *Prothrombinolysis* is the other factor to be considered in poorly clotting blood, plasma (e g after citrated storage), or exudates. Prothrombinolysis may precede or accompany fibrinogenolysis. A simple test with thrombin will quickly show up any fibrinogen present. If this is negative, fibrinogen should be added,^{69, 67} but otherwise this is unnecessary, before going on to a test for prothrombin by the addition of optimal amounts of calcium and thromboplastin (e g, the Quick test⁶⁸).

We have long been aware of the prothrombinolytic action of trypsin,³⁰ and Seegers and Loomis⁶⁰ have recently noted this with tryptase ("fibrinolytic enzyme"). Some evidence of prothrombinolysis is observed with the high-potency tryptase in the activation tests (T_5) of table 16, but the phenomenon is best seen on incubating prothrombin solution with tryptase and testing samples, at intervals, for activation with $\text{Ca} + \text{tpln}$ (table 19). The data of table 19 clearly show the progressive weakening of the prothrombin by the added tryptase.

TABLE 20—*Thrombinolytic Action of High-Potency Plasma Tryptase*

TL thrombin-lysis mixt, containing 1 cc thrombin (type specified—see Reagents), 1 cc trypt D, and buffer (to 2.5 cc vol). Incub (of TL) and clotting tests at room temp C t (sec) 0.25 TL + 0.5 B F (0.25%). Tryptase used in 1, 3, 5, buffer only (controls) in 2, 4, 6.

IV *Thrombinolysis*. Trypsin (pancreatic) also causes thrombinolysis akin to the natural irreversible disappearance of thrombin in serum.³⁸ We have noted, however, that this requires rather large amounts of trypsin.²⁰ Several recent workers,^{60, 46} claim that thrombinolysis is not produced by tryptase. In the light of the trypsin data (e g, tables 4 T_4 , 7 T_5 , T_6 , T_7 , 9 T_3 , but cf 13, T_4 -with small amount of trypsin) we were rather surprised at these claims and at our similar negative tests, on a number of occasions (e g, table 14, T_3). Very recently we have obtained some high-potency dog plasma tryptase (trypt D) (see *Reagents*). One of these preparations tested at 39 C (without control), in T_4 of table 12, was highly suggestive, but convincing evidence of the thrombinolytic action, even at room temperature, was given by an even better tryptase preparation tested on half a dozen different thrombins, including T_1 , T_3 , and T_9 of table 16, and the commercial thrombins shown in table 20. The perfect stability of the controls and the potency in clot-lysis (and in fibrinogenolysis) of the tryptase are brought out in the data. One incidental finding was that thrombinolysis could not be followed beyond a certain point, because the tryptase, persisting in the lytic mixture, destroyed the

fibrinogen in the clotting-test mixture more rapidly than the erstwhile potent thrombin could clot it. A definite shortening of the fibrinolytic times in the tests prior to this, i.e., while the thrombin, though weakening, was still present, could be ascribed to the same cause. *Trypsin inhibitors* (T I and S B I) prevent the thrombinolytic effect.

V *Lysis of accelerator globulin* (see Addendum) is another possibility.

SUMMARY

A number of high-potency purified prothrombin preparations,⁶¹ in 0.2-0.5 per cent solution in borate buffer (pH = 7.7), maintain for days or weeks a stable thrombin-forming ability, whether (a) with buffer alone, (b) with brain thromboplastin suspension, (c) with CaCl_2 . Nevertheless, they all contain a trace of thrombin and continue to activate spontaneously at a very slow rate. Optimal addition of Ca-salt somewhat accelerates this and usually leads to maximal (complete) thrombin formation in 2-11 days at room temperature. Except in a few cases, where ionized Ca^{++} is demonstrable, thromboplastin, alone, is without effect, but added *with* calcium, it completes the activation in a matter of minutes or hours depending principally upon the concentration used.

Experimental analysis of the activation process stresses the participation of (1) Ca-ions, (2) thromboplastic P-lipid factor (cephalin), (3) plasma and tissue trypsin (proteolytic enzyme). Each of these factors is studied in detail with reference to mode of action, optimal concentration, side-effects, and relation to inhibitors.

Inhibition of prothrombin activation may be considered under the following heads: (1) 'decalcifying' agents (e.g., oxalates, citrates, etc.), which (a) depress Ca-ionization and thus prevent thrombin formation, and (b), *under special circumstances*, reverse the process of activation, (2) 'antithromboplastic' (? anticephalin) agents, (e.g., heparin, and probably soybean trypsin-inhibitor, to some extent), (3) 'antitrypsin' agents (e.g., crystalline trypsin-inhibitors from pancreas and soybean), which inhibit the thromboplastic enzyme (accessory factor). Excess Ca^{++} slows rate of thrombin formation.

The evidence suggests that thrombin formation proceeds via an 'intermediary' calcium-prothrombin-cephalin (thromboplastic phosphatide) complex or compound. The amounts of (a) thromboplastic P-lipid (cephalin or 'thromboplastin') and (b) Ca^{++} determine both the rate of activation and the final thrombin yield. However, the ultimate ('ripe') thrombin owes none of its activity to the presence of any calcium or phospholipid.

The three types of activator (Ca, thromboplastin, and thromboplastic enzyme) occur as 'trace impurities' in prothrombin preparations, but Seegers' most purified materials are trypsin-free. Trypsin (and trypsin) are 'thromboplastic' only in the presence of adequate calcium and phospholipid factors, which may, however, be 'mobilized' from protein combination, including prothrombin. In this way the two basic activators are, in a sense, 'catalyzed' in their prothrombin-activating reactions.

The significance of proteolytic actions (fibrinolysis, fibrinogenolysis, prothrombinolysis, and sometimes thrombinolysis) by natural trypsin of plasma and tissue

origin is investigated and discussed in relation to the broader aspects of the blood-coagulation problem

ADDENDUM

Since this paper was submitted for publication, an entirely new aspect of the process of prothrombin activation has been opened up by the discovery of a new clotting factor, variously designated, but which may be referred to by the term *accelerator globulin* (Ware, Seegers et al.) Dr Seegers assures us that all the prothrombins here reported on contain an abundance of this factor (which is extremely potent). Further, the strength of our prothrombin solutions and the experimental conditions noted make it improbable that the data herewith reported will be invalidated by increasing knowledge of the new factor. One possible exception is the change in activation properties in some of the prothrombins discussed.

ACKNOWLEDGMENTS

We are especially indebted to Dr W. H. Seegers (Wayne University, Detroit) for his help and advice with regard to prothrombin preparations. The project owes much also to the workers of a number of other laboratories who have assisted in supplying materials (see *Reagents*) and to whom we render a sincere appreciation.

The human plasma fractions used in this work were prepared from blood collected by the American Red Cross under contract between Harvard University and the Office of Scientific Research and Development. The figures are reprinted by permission of the original publishers cited.

This paper is the fourth of a series of studies on Enzymes and enzyme-inhibitors in relation to blood-coagulation and hemorrhagic diseases, aided by a grant from the John and Mary R. Markle Foundation.

THE EFFECT OF INTRAVENOUS INJECTION OF TRYPSIN INHIBITOR ON THE COAGULATION OF BLOOD

By H J TAGNON, M D , AND J P SOULIER, M D

THE TRYPSIN inhibitor isolated from soya bean flour by Kunitz¹ has been shown to have anticoagulant activity in vitro ^{2 3} The present communication deals with the effects of the intravenous injection of this material into experimental animals The action on the clotting time, the prothrombin time, and the antitryptic activity of blood plasma and serum were studied

METHODS

Trypsin inhibitor A crude preparation was obtained by the method described previously ² Dialysis of the final preparation for twenty-four hours against saline in the ice-box was found to be necessary for the removal of a toxic factor present in the undialyzed material Without dialysis, small amounts (0.5-1 cc) of the material regularly killed the 5-pound rabbits in a very short time (30 to 60 seconds) with cardiac standstill in diastole It is possible that the toxicity was due to the presence of potassium ions in the preparation

The final preparation was spun at 2500 rpm for 15 minutes in order to remove all insoluble material, and the pH was adjusted to 7.4 by the addition of NaOH N/10 Enough material was prepared in one batch so that all experiments except one (in which the crystalline inhibitor was used) were carried out with the same batch of material It was kept frozen at -30°C and warmed up to 37°C shortly before the injection was given

The preparation of inhibitor was assayed against crystallin trypsin (obtained from the Plaut Research Laboratory, Bloomfield, N. Y.) by the method of Anson ⁴ Twenty-five milligrams of this trypsin preparation produced 0.1137 mg of tyrosin in 10 minutes at 25°C The addition of 0.2 cc of the inhibitor preparation used in this work to this quantity of trypsin reduced the production of tyrosin from 0.1137 mg to 0.0108 mg

A small quantity of crystallin trypsin inhibitor, recrystallized 3 times, obtained by the method of Kunitz¹ was used in one single experiment as indicated below

Experimental animals 2 mongrel dogs and 3 rabbits received injections of the inhibitor preparation One additional rabbit was injected with the crystallin material The animals were anesthetized by the intravenous injection of from 25 to 35 mg of nembutal per kg Injections were made into the jugular vein in the dogs and the ear vein in the rabbits Blood samples were obtained by syringe and needle from the other jugular vein in the dogs and from the carotid arteries in the rabbits The blood samples were taken simultaneously with and without anticoagulant A mixture of 2 parts of potassium oxalate and 3 parts of ammonium oxalate in dry form was used as an anticoagulant Ten milligrams of the mixture was used for every 5 cc of blood The plasma was removed immediately by centrifuging

The clotting time was studied on blood taken without anticoagulant by a modification⁵ of the method of Lee and White ⁶

The prothrombin time was measured on the plasma by the method of Quick ⁷

The presence of an anticoagulant in the samples showing a prolongation of the clotting time was tested as described previously ⁸

In the experiments on rabbits the samples of plasma were tested for their antitryptic activity before and after the injection of trypsin inhibitor preparation One half cubic centimeter of oxalated plasma was mixed with one half cubic centimeter, of a solution of crystallin trypsin and the proteolytic activity of

From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston, Massachusetts, and the Sloan Kettering Institute of the Memorial Hospital for the treatment of Cancer and Allied Diseases New York, New York

the mixture measured on a hemoglobin substrate by incubation at 37°C for ½ hour, according to the method of Anson.¹ The crystallin trypsin was the same used for the assay of the inhibitor.

In the experiments on dogs the samples of blood serum were tested before and after the injection of trypsin inhibitor for antiproteolytic activity against the blood plasma enzyme. As shown previously, the trypsin inhibitor from soy and bean is also inhibitor towards the blood plasma enzyme.² This was done by measuring the rate of dissolution of 0.1 cc of fibrinogen solution by a chloroform plasma preparation (containing the active plasma proteolytic enzyme) in the presence of each sample of serum, as described previously.

RESULTS

Tables 1 and 2 show the overall results obtained in the experiments on two dogs and four rabbits.

1. *Effect on clotting time* There was an immediate prolongation of the clotting time following the injection of the soya bean preparation in dogs as well as in rabbits. This effect was transient, lasting from forty minutes to one hour, after the injection of respectively 8 cc per Kg and 5 cc per Kg into the 2 dogs, and from 30 to 60 minutes in the 3 rabbits that were followed longer than one hour.

TABLE 1.—*The Effect of the Intravenous Injection of Trypsin Inhibitor on Clotting Time, Prothrombin Time and Fibrinolysis*

Dog #	Trypsin inhibitor (cc)	Clotting time at 37° Intervals**						Prothrombin time Intervals**						Time of lysis of fibrinogen in presence of serum from blood taken at stated intervals*					
		1	2	3	4	5	6	1	2	3	4	5	6	1	2	3	4	5	6
1 16 Kg	85	8	55	40	24	22	9	7	10	9	5	9	5	9	5	9	5	3	106
2 10 Kg	80	10	52	13	11			14	16½		16½	16½		11	180*		180*	120	76

* 0.1 cc fibrinogen + 0.1 cc serum + 0.4 cc chloroform plasma preparation

** 1 before injection, 2 from 5-10 minutes after injection, 3 from 10-30 minutes after injection, 4 from 30-40 min after injection, 5 from 46-60 min after injection, 6 from 60-90 min after injection

The injection of the small available quantity of crystallin inhibitor into rabbit #4 produced a small prolongation of the clotting time (table 2, exp 4).

2. *Effect on prothrombin time* This was prolonged following the injection into dogs and rabbits and remained prolonged for a longer period than the clotting time (tables 1 and 2).

3. *Effect on antiproteolytic activity* of blood serum and blood plasma. In the 2 experiments on dogs a chloroform plasma preparation (containing the active plasma proteolytic enzyme) was mixed with serum from blood obtained before and after the intravenous injection of trypsin inhibitor, and the mixture was tested for fibrinolytic activity on a solution of fibrinogen. Table 1 shows that the time for complete fibrinolysis of the clot increased sharply in the presence of serum from blood obtained immediately after the injection of the inhibitor. The time of fibrinolysis was still considerably prolonged at the end of the 2 experiments (table 1).

Figure 1 presents the results of experiment 1 in graph form.

the presence of samples of plasma showed a sharp decrease with plasmas obtained after injection of the inhibitor (table 2). There was a gradual disappearance of th-

increased antitryptic effect of plasma and normal or near normal values were obtained between 1 and 2 hours after the injection. Figure 2 shows the results of experiment #4 (table 2) in graph form.

FIG. 2. THE EFFECT OF INTRAVENOUS INJECTION OF CRYSTALLIN TRYPSIN INHIBITOR ON ANTI TRYPTIC ACTIVITY OF BLOOD PLASMA, CLOTTING TIME AND PROTHROMBIN TIME

TABLE 3 —*Protamine Titration of Plasma after Injection of Soya Bean Preparation*

One-tenth cc of citrated plasma obtained from blood showing a prolonged clotting time following the injection of soya bean preparation was added to varying quantities of protamine. The plasma was recalcified and the clotting time noted.

Protamine	Clotting time at 37 C	
	Dog #2	Dog #3
0	8	10
0 01	30+	30+
0 004	30	10
0 001	11	9
0 0005	11	9
0 0001	11	7

In order to rule out the presence of heparin in blood showing a prolonged clotting time following the intravenous injection of soya bean preparation, a protamine titration was carried out on the plasma from such blood in the 2 experiments on dogs. Table 3 gives a typical example of such a titration in dog #2. The results

show that there was no significant shortening of the clotting time of the recalcified plasma by the addition of various quantities of protamin

DISCUSSION

The data show that a soya bean preparation containing the trypsin inhibitor produced the following effects when injected intravenously into 2 dogs and 3 rabbits: it prolonged the clotting time of the blood, the prothrombin time of the blood plasma, and increased the antiproteolytic activity of the blood serum or plasma. The same effects were obtained in one experiment on a rabbit, in which a highly purified, three times recrystallized trypsin inhibitor preparation from soya bean was used.

There was some parallelism among the effects of the injection on the clotting time, the prothrombin time and the antiproteolytic activity of the plasma. This parallelism was most apparent in the experiments on rabbits because they were conducted for a longer time than those on dogs. The coincidence of the three actions appears clearly in figure 2.

The one single experiment carried out with the purified material gave results essentially similar with those obtained with the cruder material.

If one considers the fact that the trypsin inhibitor produced all these effects when added to blood *in vitro*², it seems that the data reported here might constitute evidence that the trypsin inhibitor prolonged the clotting time *in vivo* by the same mechanism by which it prolongs it *in vitro*, and not indirectly by provoking the organism to release an anticoagulant in the blood stream. This is further confirmed by the fact that the blood showing a prolonged clotting time following the injection of the trypsin inhibitor did not contain any heparin in the two experiments in which a protamin titration was carried out. It is well known that the prolongation of the clotting time following the intravenous injection of peptone or of antigen in sensitized animals is due to the appearance of heparin in the blood of such animals.

Three different trypsin inhibitors so far have been reported as having anticlotting properties: the trypsin inhibitor from pancreas,¹⁰ from blood serum,¹⁰ and that from soya bean.² These three substances differ chemically and their similar action on the blood coagulation mechanism parallels their similar action on trypsin. It is to be noted that the trypsin inhibitor from soya bean and from pancreas also inhibits the proteolytic enzyme of blood plasma.^{11, 12} The exact role of the plasma enzyme in blood coagulation is unknown: a recent communication presents evidence that the enzyme has no clotting activity by the usual tests.¹² It is nevertheless interesting to note that these substances which inhibit the proteolytic action of the enzyme also are anticoagulant agents.

The practical use of the trypsin inhibitor from soya bean for anticoagulant therapy must await further study. The material does not appear to be toxic and could conceivably be used, in purified form, for prolonging the clotting time *in vivo* when such action is desired. However it is quite possible that the inhibitor is antigenic and this point should be clarified before an attempt at practical application is made.

SUMMARY

1 The intravenous injection of a soya bean preparation containing a trypsin inhibitor into 2 dogs and 3 rabbits produced the following effects prolongation of the clotting time and of the prothrombin time, and increase in the antiproteolytic activity of the blood plasma or serum

2 Identical results were obtained in one experiment in which a crystallin trypsin inhibitor from soya bean was used

3 The significance of these results is briefly discussed

FIBRINOLYSIS ITS MECHANISM AND SIGNIFICANCE

By R. G. MACFARLANE, M.D., AND ROSEMARY BIGGS, M.B., Ph.D.

INTRODUCTION

THE BIOLOGIC processes that produce a gross physical change have always attracted much interest. The transformation of fluid blood to solid clot, for instance, has been the subject of experiment and discussion the amount of which seems disproportionate to its fundamental physiologic importance. There is, however, a converse to this process of coagulation which, though equally obvious in its result, has been comparatively neglected, possibly because in its extreme form it occurs only rarely and with apparent irregularity. This is the phenomenon of fibrinolysis or dissolution of blood clot that, though normally slow, may occur with great rapidity under certain conditions. Though there has been relatively little work on this subject recent developments have made it possible to appreciate part of the mechanism that underlies it, and to realize that factors are involved which are of basic importance. It is apparent also that the process of fibrinolysis is linked with other subjects previously without obvious association, and this paper, though it cannot claim to be a complete review, is presented as an attempt to assemble relevant information, and to relate it to some observations of our own.

DEFINITION

For the purpose of this communication fibrinolysis is taken to mean the aseptic dissolution of fibrin brought about by the direct action of a mechanism existing in normal blood. Usually dissolution may take days or weeks to complete, but may be so accelerated as a result of natural changes occurring in the living subject or of experimental procedures as to occur within a few hours or minutes. This increased activity is the main subject dealt with, and though a particular set of factors have been studied as being apparently those mainly responsible, it is recognized that others may be involved.

THE RECOGNITION OF FIBRINOLYSIS

It is an ancient observation that circumstances may modify the permanence or stability of blood clots. Zimmermann (1846) found that ox fibrin suspended in salt solution remained intact for up to 10 days, while fibrin from human blood obtained by wet cupping dissolved in 12-24 hours. He refers to earlier observations of a similar nature by Denis (1838). Green (1887) also studied the disappearance of fibrin in saline, which occurred without obvious bacterial action, and found that once it had disintegrated fibrin could not be made to clot again by adding thrombin. Similar observations on the blood of dogs subjected to hemorrhage were made by Distre (1893, 1894 a & b, 1895), who, apparently the first to use the term fibrinolysis, came to the conclusion that fibrin is digested and not dissolved, though he did not favor the idea of a lytic enzyme in blood. Rulot (1904) believed

From the Radcliffe Infirmary, Oxford, England

that leukocytes were concerned in the digestion, since an increase in their concentration hastened the reaction. In 1905, Nolf began a series of experiments in which he induced fibrinolytic activity in dogs by various procedures, including hepatectomy and peptone shock. He regarded this work as demonstrating the participation of a proteolytic enzyme in the process of blood coagulation to which he believed fibrinolysis was a logical, if unusual, sequel. Morawitz (1906) studied the familiar phenomenon of the fluidity of the blood in cases of sudden death. He observed that blood from such cases contained itself no fibrinogen, and was capable of destroying the fibrinogen and fibrin of normal blood. Hirose (1934) supported Nolf in regarding the lysis of fibrin as the result of coagulation and also considered that it was the cause of clot retraction.

In 1937, Yudin stimulated a considerable new interest in fibrinolysis by its practical, if rather macabre, application to a blood transfusion service in Russia. It was the practice to use the blood from fresh corpses, and for obvious reasons the most suitable donors were the victims of accidental or sudden death rather than those who had died from a long drawn-out disease. This selection of subjects proved to have another advantage, for in these cases of sudden death the blood removed from the body, though it clotted in the usual way, reliquified within a few hours and could be used for transfusion without anticoagulant. Since it appeared that shock might be a relevant factor in Yudin's subjects, Macfarlane (1937) investigated the occurrence of fibrinolysis in living patients who had undergone surgical operation. There was an occasional instance of rapid lysis of whole clotted blood, but this was a rare and apparently capricious occurrence. It was found, however, that fibrin prepared from diluted plasma disappeared rapidly in a high proportion of post operation cases, though similar preparations made before operation were stable for weeks, an observation that was soon confirmed by Imperati (1937) and later by Kaulla (1947). Mole (1943) and Wexler and Ellis (1944) confirmed the occurrence of fibrinolytic activity in the blood of cases of sudden death. Though Smith and Smith (1945) and Wilson and Munnell (1946) have reported that blood taken during menstruation shows fibrinolytic activity, which also occurs, according to the latter workers, in hypertension and eclampsia, the technic used makes it difficult to assess the significance of these observations. Tagnon, Levenson, Davidson and Taylor (1946) have observed fibrinolysis in human cases of severe burns and in one case of fatal narcotic poisoning, and have been able to induce similar activity in the blood of dogs by severe hemorrhage. They quote an observation by Ham that fibrinolysis sometimes follows the intravenous administration of typhoid vaccine in human beings.

THE MECHANISM OF FIBRINOLYSIS

From these scattered observations it is clear that rapid dissolution of fibrin occurs following a variety of disturbances to the living organism which may be due to an acceleration of the normal, slower process, or to some other agency. The fact that lysed fibrin is irreversibly altered, coupled with the observations of Morawitz (1906) and Mole (1943) makes it probable that fibrinolysis is the result of proteolytic digestion, and it would be logical to trace the recognition of a proteolytic

enzyme in normal blood. Since fibrin in sterile whole blood usually remains intact for some days or weeks it follows that such an enzyme, if it exists, must be under normal conditions relatively inert, though capable of activation.

ACTIVATION BY CHLOROFORM

In 1889 Denis and Mirbair found that a thermo-labile proteolytic agent developed in serum after the addition of chloroform, ether or thymol, apparently the first observation of a phenomenon since much studied. Delezenne and Pozerski (1903) investigated this reaction further, showing that serum after admixture with chloroform developed the power of digesting gelatin and casein, an activity that was inhibited by the addition of untreated serum. They came to the conclusion that a proteolytic enzyme present in the serum was normally inhibited by some other substance which was removed or destroyed by chloroform, a suggestion that could be related to previous observations by Hildebrandt (1893) and Hahn (1897) that normal serum is capable of inhibiting proteolysis by trypsin.

Jobling and Peterson (1914) came to the conclusion that the antitrypsin of plasma was soluble in lipid solvents, a view which has recently been revived by Ungar (1945). Dale and Walpole (1916) and Yamakawa (1918) confirmed the destruction of the inhibitor by chloroform, and Opie, Barker and Dochez (1911) found that the administration of chloroform by stomach tube to dogs resulted in protein digestion occurring in serum samples, and apparent destruction of fibrinogen. Nolf (1921 a & b, 1922) found that proteolytic activity accompanied by fibrinolysis could be generated in mammalia and bird plasma by the action of chloroform. The action has been extensively investigated by Tagnon (1942) and Tagnon, Davidson and Taylor (1942), mainly from the point of view of its relation to blood coagulation. They found that the globulin fraction from chloroform serum was strongly fibrinolytic, and might destroy fibrinogen before clotting could occur.

FRACTIONATION OF PLASMA

The fact that separation of the plasma proteins may result in proteolytic activity has also long been recognized. Hedén (1904b) fractionated ox serum by ammonium sulphate precipitation, and found that the globulin contained a proteolytic enzyme that was inhibited by a thermo-labile factor associated with the albumen fraction. Opie and Barker (1907) confirmed these findings, and observed the similarity between the globulin enzyme and leuko-protease. More recently Feissly (1942) and Macfarlane and Pilling (1946a) have studied the fibrinolytic activity of globulin fractions separated by acid precipitation. Taylor et al. (1945), who have studied plasma fractions provided by Professor Cohn and Dr. Edsall, have observed spontaneous proteolytic activity associated with fractions 1 and 111-2. It is probable that fractionation separates an enzyme-inhibitor complex, analogous to the dissociable trypsin-antitrypsin compound studied by Hussey and Northrop (1923). The relationship in the latter case obeys the mass-action laws, and dissociation may occur following simple dilution of the complex, a fact which is also relevant to the plasma enzyme and its inhibitor.

Separation of the enzyme and inhibitor has also been accomplished by the use

of trichloroacetic acid Schmitz (1937) found that the enzyme was precipitated by this agent, while the inhibitor remained in the supernatant fluid. He came to the conclusion that fibrinolysis was due to the adsorption of the enzyme together with a kinase onto fibrin. Tyengar and Sehra (1942) have also utilized trichloroacetic acid in the estimation of enzymatic activity of plasma in a variety of conditions. Mole (1943), working with blood from cases of sudden death, found that the rapid fibrinolysis was due to the action of an enzyme precipitable by trichloroacetic acid. This enzyme resembled trypsin in some respects, but was shown to be significantly different in others.

Separation of the enzyme has also been accomplished by adsorption onto fibrin. Barker (1908) studied the proteolytic enzyme associated with fibrin, and Rosenmann (1922, 1936, 1937) has used lysed fibrin as the source of an enzyme preparation that he has studied extensively, finding it apparently identical with the agent present in the globulin fraction and active at pH 7.3-7.8. Macfarlane and Pilling (1947b) have also utilized the adsorption of the enzyme by fibrin. The globulin fraction of plasma is added to a solution of fibrinogen subsequently clotted by thrombin. The resulting clot is removed, washed free of protein, and allowed to lyse in saline when the enzyme is released into solution.

Following fractionation by electrophoresis most of the enzyme is found in fraction III²⁻³ (Cohn et al. 1944, Edsall, 1947).

ACTIVATION BY STREPTOKINASE

The procedures described above have produced activation of the plasma enzyme by destruction of its inhibitor, or by separation of the enzyme-inhibitor complex. Recently, observations have been made that provide an important link between fibrinolysis occurring as a result of these manipulations or of natural causes in the living subject, and fibrinolysis produced by the culture filtrate of certain strains of *ρ*-haemolytic streptococci. In 1933, Tillett and Garner had shown that human plasma, if allowed to clot in the presence of such filtrates, underwent very rapid fibrinolysis. The plasma of patients who had recovered from streptococcal infections and rabbit plasma resisted this lysis. They found, however, that if rabbit fibrin was clotted by human thrombin it became susceptible to lysis by the streptococcal filtrate. Milstone (1941) showed that pure fibrinogen, even if derived from human blood, yielded fibrin which was resistant to the action of streptococcal filtrate, but that if a small amount of the globulin fraction from human plasma were added lysis occurred as with whole plasma. He also found that the addition of such globulin to rabbit plasma resulted in lysis of this fibrin by the filtrate. He therefore postulated a lytic factor present in the globulin of human blood which was necessary to sensitize fibrin to the action of the bacterial enzyme. In 1944, Kaplan came to the conclusion that Milstone's 'lytic factor' and the proteolytic factor activated by chloroform were identical. This suggestion was confirmed and extended by Christensen (1945) and Christensen and MacLeod (1945). These workers showed that the enzyme liberated in plasma or serum by the action of chloroform was the same as that which appears following the addition of streptococcal filtrate. The enzyme is proteolytic, being capable of digesting fibrin, fibrino-

gen, casein and gelatin and, though it resembles trypsin, is distinct from it. It is inhibited by the so-called trypsin inhibitor of plasma and by the pancreatic anti-trypsin of Kunitz and Northrop (1936). The enzyme is present as an inert precursor associated with the globulin fraction of the plasma and its inhibitor is associated with the albumen. They postulated that streptococcal filtrate contains a kinase capable of activating the precursor so that the inhibitor is overwhelmed. Kaplan (1946) confirmed the distinction between the plasma enzyme and trypsin by showing that the streptococcal kinase did not activate trypsinogen nor did entero-kinase activate the plasma enzyme. Macfarlane and Pilling (1946a) in observations in which plasma and plasma fractions were treated with streptococcal filtrate and chloroform, came to the conclusion that plasma normally contains not only the enzyme precursor and its inhibitor, but free enzyme. They showed that simple dilution of whole plasma will, if there is an increase in free enzyme, result in the development of activity, resulting from dissociation of the enzyme-inhibitor complex.

TERMINOLOGY

In the course of previous work on the proteolytic factor of serum during the past 40 years, different terms have been applied to what is almost certainly the same substance. This has led to confusion and it is desirable that a unified terminology should now be adopted. Such names as serum trypsin, serum protease, serum tryp-tase, fibrinolysin, thrombolysin and others should be abandoned in favor of a more specific designation. The nomenclature proposed by Christensen and MacLeod (1945) seems to fulfil the necessary requirements. In this the proteolytic enzyme of the plasma is called "plasmin" a choice for which good reasons are given. The precursor of plasmin is termed "plasminogen," and the streptococcal filtrate factor previously called 'fibrinolysin' now becomes "streptokinase." The antibody developed by patients recovering from streptococcal infection, which is capable of neutralizing streptokinase, is called "antistreptokinase." The inhibitor of proteolytic enzymes present in normal plasma might be called "antiplasmin" for the sake of uniformity, though such a name implies a sense of restriction with regard to its activities which is undesirable. An alternative nomenclature proposed by Loomis, George and Ryder (1947) in which the term 'fibrinolysin' is applied to the plasma enzyme, seems to us to be fraught with danger of confusion since this term has, in the past, been applied to the streptococcal factor.

THE PROPERTIES OF PLASMIN

The identity of plasmin with the enzyme activated by chloroform apparently is established (Christensen and MacLeod 1945). The enzyme studied by Mole (1943) in cases of sudden death, and that occurring in the plasma of patients after operation or other disturbance (Macfarlane and Pilling, 1947b) are so similar to plasmin with regard to their physical properties and activity that it may be assumed, as a working hypothesis, that fibrinolysis, whether induced by streptokinase, chloroform, fractionation, or disturbances in the living subject, is due to active plasmin. It has already been shown that plasmin is capable of lysing fibrin, and of digest-

ing fibrinogen, gelatin and casein. With regard to fibrinolysis, though preformed fibrin may be slowly digested activity is greatly increased if the enzyme is present during the process of coagulation, probably because of the strong adsorption of plasmin by fibrin during clotting. Though plasmin is capable of digesting other proteins, its fibrinolytic action is more rapid in proportion to such digestion than is the case with trypsin and other proteolytic enzymes. Fibrinolysis, therefore, is a delicate indicator of plasmin activity which has been used by Macfarlane and Pilling (1946a) for quantitative estimations. This method allows, however, of only an arbitrary expression of activity, which, in this case has been in terms of the greatest dilution of the enzyme that will produce lysis within 24 hours at 37°C of the clot formed by a 0.075 per cent solution of pure fibrinogen.

Other methods of determination of activity used by previous workers include estimation of the increase in nonprotein nitrogen following incubation of the enzyme with a particular substrate, which, in some cases has been merely whole serum, in others casein, gelatin or hemoglobin. Viscometric determinations have been made with casein and gelatin, but we ourselves have found this technic unreliable, even under rigidly controlled conditions. Estimation of acid soluble tyrosine by the method of Anson and Mirsky (1937) has given satisfactory results. We have found, by this method, that plasmin is capable of digesting all the proteins of normal plasma, a fact which may have some significance in the physiologic effects of its activity.

The pH of optimum activity of plasmin is about 7.4, and of maximum heat stability between 7 and 7.4. The enzyme is destroyed at this pH by heating to 55°C for twenty minutes. It is nondiffusible through cellophane and behaves, with regard to precipitation, like the globulin of plasma. It is precipitated by half saturation with ammonium sulphate, full saturation with sodium sulphate or by bringing the pH to 5.5 after dialysing the plasma free from electrolytes. It is precipitated by trichloroacetic acid, and by acetone and alcohol with moderate loss of activity, and it is strongly adsorbed by fibrin.

INHIBITION OF PLASMIN

Antiplasmin, the natural inhibitor of plasmin, is associated with the albumin fraction of the plasma. It is said not to be precipitated by trichloroacetic acid, but Duthie (1947) does not agree with this statement. The inhibitor is nondiffusible through cellophane and heat labile, being destroyed by heating to 66°C. It is rapidly inactivated at pH values below 5.0, but is stable in the alkaline ranges. It is destroyed by chloroform, ether, alcohol and acetone (Duthie 1947). As with pancreatic antitrypsin and trypsin, the plasmin-antiplasmin complex appears to be dissociable by simple dilution unless there is a considerable excess of inhibitor (Macfarlane and Pilling 1946a), and simple fractionation of the plasma into albumin and globulin is also apparently capable of splitting the complex. The activity of the inhibitor must be considered in any study of fibrinolysis, since the equilibrium it maintains with plasmin may be disturbed by changes in either factor. We have attempted to estimate antiplasmin activity by means of the inhibitory effect of the albumin fraction to be studied on the digestion of fibrinogen and casein.

by purified plasmin Plasmin is also inhibited by the crystalline antitrypsin of Kunitz and Northrop (1936) by heparin and by the soya bean trypsin inhibitor of Kunitz (1946), the latter being most effective Grob (1943) has reviewed the literature on the antiproteolytic factor of serum

OTHER ENZYMES POSSIBLY RELATED TO PLASMIN

The characterization of plasmin has not, at present, been sufficiently specific to determine whether or not certain other enzymes, which have been described in body fluids and tissues, are identical Since it is possible that these enzymes may enter the blood stream or, like plasmin, become activated from inert precursors, they may be briefly considered

Hedin (1904a) identified two proteases in spleen tissue, one acting at a slightly alkaline pH and inhibited by serum, as was the "leucoprotease" of Opie and Barker (1907) There has been a large number of publications by Abderhalden (1921, 1940 etc) and his associates dealing with the presence of various proteolytic enzymes in the blood and tissues which they believe to be specific for abnormal tissues Patients with carcinoma, for instance, produce enzymes specifically digesting carcinomatous tissue, and in pregnancy there is an enzyme capable of lysing placental tissue It is probable that part, at least, of these findings depend on the activation or inhibition of plasmin, but the whole subject of the Abderhalden reactions is too voluminous to be dealt with adequately here Grassmann and Heyde (1930) have described peptidases in animal serum or plasma active between pH 7 and 8 that split leucylglycyl glycine which are increased in various pathologic states Rosenmann (1936) has extracted a fibrinolytic enzyme from liver, kidney, lung, pancreas and thyroid tissue closely resembling his "thrombolysin" Maschmann (1942) has found that rats with sarcoma may have a higher level of blood peptidase than is normal Huggins, Vail and Davies (1943) have studied fibrinolysis in menstrual fluid finding considerable activity which is also present in extracts of endometrium, prostate and thyroid tissue Zamechick, Stephenson and Cope (1945) have found that lymph from the extremities of dogs contains an amino-exopeptidase which is increased in amount if the limb is traumatised or burned They have also found that blister fluid from burns in human cases contains the same enzyme, but Macfarlane (1943) failed to find fibrinolytic activity in blister fluid Beloff and Peters (1945) have investigated a protease extracted from human skin active at pH 6-8 This enzyme is not trypsin and does not split leucylglycyl glycine, and following burning its concentration in the affected skin is decreased Beloff (1946) has studied an inhibitor of this enzyme present in the albumen fraction of normal plasma, but considers that this is distinct from antitrypsin It is not clear, however, that this conclusion is justified Fruton (1946) who has made an extensive study of the tissue enzymes has found two leucine aminopeptidases in lung, serum and skin extracts

Macfarlane and Pilling (1947b) have examined human tissues for the presence of fibrinolytic activity The tissues were perfused, if practical, with running water until the vessels were blood free, minced, extracted with saline and the enzyme precipitated with ammonium sulphate or acid The precipitates were dissolved

and tested for fibrinolytic activity. This varied from one sort of tissue to another, and from case to case, but, in general, it was found that lung extract had the greatest activity being, in many cases, relatively greater than the blood plasmin activity of the same subject. This lung enzyme resembled plasmin both as regards its physical properties and its reaction with the inhibitors, but its action on pure substrates has not been investigated. Fibrinolytic activity was also observed in extracts of kidney, suprarenal and thyroid but in a lesser degree, and it was found that in all tissues the highest yields occurred in cases of sudden death when the blood plasmin level was also increased (fig. 1).

The inhibitory power of the albumin fraction of organ extracts have also been estimated (fig. 2). It has been constantly found that spleen extract has a potent inhibitory effect on plasmin and lung extract resembling that of antipiasmin. This

FIG. 1. Histogram showing the mean plasmin activity of extracts from various tissues and organs (a) from cases of sudden death (solid columns) (b) cases of slow death (hatched columns). The unit of activity is based on the titre of the enzyme (see text).

finding is of interest in view of the work of Ungar (1945) in which the injection of splenic extracts raised the antitryptic power of the serum.

It has been observed that there is a fibrinolytic enzyme in normal urine (Macfarlane and Pilling 1947a). This enzyme again resembles plasmin in its properties. Though the concentration of this enzyme in the urine is not closely correlated with the plasmin level of the blood, and though it differs slightly from plasmin in being heat stable and more affected by trypsin inhibitors, it is possible that it is, in fact, plasmin in the process of elimination. Other enzymes resembling pepsin have been described in urine, the literature being reviewed by Farnsworth, Speer and Alt (1946).

THE ACTIVATION OF PLASMIN IN VIVO

Though normal plasma may be activated in vitro by the procedures described previously, in its natural state it possesses no demonstrable proteolytic activity,

though this may develop following a variety of circumstances disturbing to the living subject. The train of events connecting these stimuli with the fibrinolytic mechanism is obscure, but since the nature of the latter is becoming clearer a more systematic investigation of the process has become possible, since it is probable, though not definitely established, that fibrinolytic activity *in vivo* is due to plasmin ^{fa.}

In his early experiments, Nolf (1905, 1908) was able to produce fibrinolysis following peptone shock in dogs in which the liver had been isolated from the circulation, thus demonstrating that this organ is not a necessary link in the chain of events leading to activation. Loeper et al (1932) found that after ligation of the renal arteries in dogs there was a loss of protein and a rise in nonprotein nitro-

FIG. 2. Histogram showing the mean antiplasmin activity of extracts of various tissues and organs (a) from cases of sudden death (solid columns) (b) cases of slow death (hatched columns). The units refer to a dried albumin standard, and do not compare to the units in Figure 2.

gen in serum during incubation. Hougardy (1934) has made the significant observation that removal of the pancreas does not reduce the proteolytic activity of the serum when treated with chloroform.

Since it seemed that the condition of traumatic shock had existed in all cases in which fibrinolysis had been demonstrated and might be the prime mover of the process, Macfarlane (1937) investigated the blood of patients undergoing surgical operation. The technic employed used diluted citrated plasma clotted by calcium chloride, it being found that in normal blood samples the fine fibrin web so formed was stable under aseptic conditions for a period of weeks. In about 70 per cent of the patients, after operation these fibrin webs disappeared in twenty-four hours or less, though control samples taken the day before from the same patients showed no undue instability. The nature of the cases showing such fibrinolysis gave little information as to the factors responsible for this change. There was no close correla-

tion between fibrinolysis and the traumatic shock experienced by the patient since quite minor operations might be accompanied by relatively intense activity, whereas major surgical procedures might give negative results. Similar results were obtained by the same technic by Imperati (1937), though the rather lower incidence of 50 per cent of fibrinolysis following operation was recorded. He, too, observed the lack of correlation between the severity of the operation and the degree of fibrinolytic activity. From these investigations it appeared that fibrinolysis is dependent on some factor commonly associated with the procedure of surgical operation, though not obviously connected with shock or trauma, but the design of the original experiment was not sufficiently controlled to allow of its identification by analysis of its results.

A further experiment was therefore carried out (Macfarlane and Biggs 1946) in which serial blood samples were obtained from each patient to control the effect of premedication, and the anaesthetic, as well as the operation itself. It was found that a high proportion of positive results were obtained before the operation, and even before the anesthetic or premedication, which could not be explained by the pathologic condition from which the patients were suffering, since trivial conditions involving no constitutional disturbance were included. The one common factor seemed to be preoperation anxiety, a conclusion which was borne out by the independent observations of Lattner (1947) who had found fibrinolytic activity in cases of anxiety states, and hyperthyroidism in a normal person during an air raid. Kaulla (1947) found that fibrinolysis occurred after the injection of novocain or even a large volume of saline, and though he believed that displacement of tissue fluid was the activating agent in this latter experiment, the effect of anxiety cannot be excluded. In addition to the operation cases it was found that positive fibrinolysis occurred in a variety of pathologic states in which hypersensitivity appeared to be the common factor, but in view of the probable effect of anxiety, such findings are not easy to assess.

The next observations (Biggs, Macfarlane and Pilling 1947) concerned the discovery that severe exercise induced fibrinolytic activity in normal subjects. This was proportional to the amount of exercise taken, and to the degree of exhaustion it induced, the latter being influenced by training. The occurrence of fibrinolysis both in exercise and in anxiety suggested, of course, that adrenalin activity might be an important underlying factor, and experiment established that intense fibrinolytic activity could be induced in normal subjects by the injection of adrenalin. The findings resembled closely those provided by exercise, since in both fibrinolytic activity appeared in the circulating blood within a minute or so of the onset of the stimulus, and disappeared within a few minutes of its cessation, and in both there was a change in the blood picture consisting of an almost immediate rise in lymphocytes, with a slower rise in polymorphonuclear leukocytes and platelets. These results provided an explanation of previous observations, since in all cases in which fibrinolytic activity has been recorded it is likely that adrenalin activity will have been stimulated. It must be determined, of course, what part adrenalin plays in the reaction. We have made observations on this matter, but they are far from complete at present. Adrenalin itself produces no proteolytic

activity of plasma *in vitro*. It is clear, therefore, that it requires the cooperation of one or more factors which exist in the body, but not in the shed blood. The obvious possibility that the rise in leukocytes or platelets were directly responsible for the increase in fibrinolytic activity has been disproved by the finding that addition, separately or in combination, of fresh lymphocytes, polymorphonuclears or platelets to normal plasma is not followed by fibrinolysis, nor does the incubation of adrenalin with these elements result in any activating factor being produced. The plasma from subjects who have developed fibrinolytic activity retains this activity after centrifuging at 20,000 rpm to remove all its formed elements. Moreover, in patients with marked polymorphonuclear leukocytosis, lymphocytosis, or thrombocytosis, no spontaneous fibrinolytic activity has been observed.

The injection of adrenalin in certain pathologic states has given some information, if largely negative, regarding the other factors concerned. A normal fibrinolytic response has been obtained in two cases of Addison's disease in which subsequent postmortem examination has demonstrated almost complete destruction of the suprarenal cortex, and one case of aplastic anemia, in three cases of splenectomy (performed for traumatic rupture) and in three cases of hemophilia. The only patients with a constantly diminished response to adrenalin are those in whom the lymph glands have been affected by Hodgkin's disease or x-ray irradiation. From these results, and those previously mentioned, therefore, it appears that given the stimulus of adrenalin, fibrinolysis is independent of the normal function of the suprarenal cortex, spleen, pancreas, or liver, but it is possible that lymphoid tissue may be involved.

The demonstrable changes that occur in the components of the proteolytic system of plasma concurrently with spontaneous activation consist of an increase of plasmin that suggest activation of plasminogen. This rise may be sufficient in extreme cases to produce fibrinolysis in the whole blood, but usually it is necessary to dilute the plasma to demonstrate the increased activity. A more puzzling finding is the apparent diminution in the inhibitor that also occurs in spontaneous activation. Figure 3 illustrates the reduction of the inhibitory effect of the albumen fraction of normal plasma, as compared with plasma from the same subject following activation by adrenalin. It appears, therefore, that the process of activation *in vivo* is more complex than the mere secretion into the blood stream of a kinase capable of activating plasminogen. Such a kinase, however, is probably concerned, and it is of interest that Astrup and Permin (1947) claim to have observed its presence in fresh tissues, though it is not clear that they have eliminated the active enzyme already present in such preparations.

THE SIGNIFICANCE OF FIBRINOLYSIS

The balance between proteolysis and its inhibition may control many of the vital processes in which blood constituents are involved. The most obvious of these are the proteolysis of pathologic fibrin deposits and the destruction of plasma proteins following the activation of plasmin. In the more complicated mechanism of blood coagulation, both proteolytic and inhibitory factors can alter the speed of clotting and some naturally occurring anomalies may be related to changes in the

plasmin-antiplasmin complex. A normal balance of proteolytic and inhibitory substances in the blood may also be necessary for the dynamic equilibrium between blood and tissue proteins which probably forms the background of protein metabolism, and the negative nitrogen balance which follows alarming stimuli such as trauma, burns, etc., may be related to the plasmin activity with which they are frequently accompanied. Proteolysis may also, under certain circumstances, lead to the liberation of harmful products of protein digestion, and the release of histamine in anaphylactic shock has been attributed to this cause.

THE DISSOLUTION OF FIBRIN

In local inflammation or trauma, fibrin is formed in the tissues, and during healing its necessary reabsorption is probably due either to the action of plasmin or

FIG. 3. Curves showing the digestion of casein by plasmin in terms of the release of acid soluble substances estimated as tyrosine. In each case a similar concentration of the albumin fraction from the blood of the same subject (1) resting, and (2) after adrenalin injection, has been added. A reduction in antiplasmin effect is observed following the administration of adrenalin.

to the proteolytic enzymes of the tissues. Similarly in pneumonia relatively large amounts of fibrin are liquified during resolution, and it is significant that the lung often contains an unusually high content of fibrinolytic enzyme. Following intravascular thrombosis the thrombus may disintegrate, a process that may be accompanied by general fibrinolytic activity which Kaulla (1947) has demonstrated in the blood of patients with thrombosis during clinical improvement. The dissolution of clots by fibrinolytic enzymes in the endometrium may be a factor in normal menstruation (Smith and Smith 1945).

CHLOROFORM POISONING

The destruction of fibrinogen by plasmin can seldom be demonstrated *in vivo* because the normal liver replaces fibrinogen with great rapidity so that when the blood of dogs is replaced by defibrinated blood, normal coagulation is restored within an hour (Whipple 1914, Goodpasture 1914). In chloroform poisoning,

which might produce plasmin activity from destruction of antiplasmin, there is a demonstrable fall in fibrinogen in five hours (Whipple 1914) and a profound deficiency in three days (Whipple and Hurwitz 1911, Whipple 1914, Smith, Warner and Brinkhouse 1937) This disappearance of fibrinogen, though usually attributed entirely to failure of regeneration, is more rapid than that which occurs without a toxic factor, as for instance, when the normal liver is excluded from the circulation (Whipple 1914), or following transfusion in a patient with afibrinogenemia when fibrinogen could still be demonstrated in the circulation after eight days (Pinniger and Prunty 1946) Denys and Marbaix (1889) were the first to suggest that the loss of nitrogen which occurs in chloroform poisoning might be due to proteolysis Opie, Barker and Dochez (1911) showed that there was an increase in nonprotein nitrogen in the incubated serum from an animal with chloroform poisoning, and Jacoby (1900) demonstrated fibrinolysis in severe phosphorus poisoning It is therefore probable that proteolysis is a factor in the loss of fibrinogen in chloroform and phosphorus poisoning

BLOOD COAGULATION

There is a considerable accumulation of evidence in favor of the view that one or more components of the fibrinolytic system are concerned in blood coagulation The fact that chloroform serum causes the clotting of fibrinogen solutions originally suggested to Nolf (1908, 1938 etc) that proteolysis might be a factor in normal blood coagulation He considered that two substances, thrombogen and thrombozyme combined in varying proportions with fibrinogen to form a clot, an excess of thrombogen and thrombozyme leading to the release of a proteolytic enzyme which might cause incoagulability from destruction of fibrinogen or coagulation followed by fibrinolysis The coagulant action of the globulin fraction observed by Tagnon (1942) suggests the participation of plasmin in blood clotting, and although its exact role has not been determined the facts available suggest an analogy between the action of plasmin and trypsin Neither purified plasmin nor trypsin will clot fibrinogen solutions (Dale and Walpole 1916, Seegers and Loomis 1947), and both apparently lead to the release of thrombin from oxalated plasma (Dale and Walpole 1916, Stephen and Wohl 1921) A further study of trypsin in relation to coagulation is therefore of interest Ferguson and Erickson (1939) have shown that trypsin causes an increased rate of conversion of prothrombin to thrombin, and Lenggenhager (1946) showed that pure prothrombin is converted into thrombin by trypsin only in the presence of an additional plasma component which he has called prothrombokinin The amount of thrombin formed by trypsin is directly proportional to the amount of prothrombokinin present He suggests that trypsin activates prothrombokinin to a substance called thrombokinin which combines directly with prothrombin in the presence of calcium to form thrombin Lenggenhager extracted a natural activator of prothrombokinin (thrombocatalysin) from plasma and found that this was fibrinolytic According to Lenggenhager, thrombin formation proceeds as follows

Lenggenhager's views are supported by various observations Feissly (1942) obtained a proteolytic component from the "acido-globuline" fraction of Dala dilhe (1937) which had the power to convert prothrombin to thrombin in the presence of calcium. He concluded that this substance was one of two components of thromboplastin, the second being a phospho-lipoid. Fantl and Nance (1946) and Owren (1947) both showed that an additional factor from the plasma was necessary for the conversion of prothrombin to thrombin.

The fact that plasmin and trypsin can coagulate oxalated plasma in the absence of added calcium makes it difficult to accept coagulation by these substances as closely analogous to that occurring normally. However, Ferguson and Erickson (1939) have shown that optimum coagulation with trypsin requires the addition of both calcium and cephalin, and Lenggenhager (1946) showed that trypsin even in concentrations of 0.25-1 per cent will not coagulate plasma which is continually in motion and suggested that its coagulant action on citrated plasma was due to a local accumulation of calcium ions released by proteolysis from an inactive form in combination with protein. Moreover, although chloroform serum will coagulate plasma and fibrinogen, there is some doubt as to whether purified plasmin has this power (Macfarlane and Pilling 1947b). Thus calcium may be necessary for coagulation with both trypsin and plasmin. The difficulty raised by Rosenmann (1937), who showed that substances probably identical with plasmin and antiplasmin could be distinguished from all known coagulant factors, does not preclude the possibility that plasmin may activate an additional plasma factor not recognised by him. The present evidence, therefore, supports the view that plasmin may be concerned in the activation of prothrombin, a suggestion which implies that one of the components of thromboplastin is proteolytic.

Indirect evidence for the proteolytic theory of thromboplastin was suggested by observations on the coagulation defect in hemophilia. Tagnon, Davidson and Taylor (1942) showed that the hemophilic globulin could not be activated by chloroform, Feissly (1942) showed that the globulin fraction was not proteolytic, and Ferguson (1939) showed that hemophilic prothrombin could be converted into thrombin in the normal time on the addition of trypsin. These observations appear to suggest a deficiency in the proteolytic component of thromboplastin, but the experiments of Tagnon and Feissly could not be confirmed by Macfarlane and Pilling (1947b), and Tagnon's results have been refuted by Lewis et al (1946). Furthermore if hemophilic patients receive an injection of adrenalin they develop a normal fibrinolytic reaction with only a slight reduction in the coagulation time of whole blood and recalcified plasma (Biggs, Macfarlane and Pilling 1947).

A study of the inhibitors of proteolysis also supports the view that proteolysis is a factor in coagulation. Ferguson (1942) and Grob (1943) showed that pancreatic trypsin inhibitor delays coagulation, and Grob (1943) showed that the delay results from an inhibition of either prothrombin or thromboplastin. Macfarlane and Pilling (1946b) and Macfarlane (1947) studied soya bean trypsin inhibitor and showed that its inhibitory effect on blood coagulation was antithromboplastic. By inference these observations suggest that thromboplastin has a proteolytic component.

Inhibition by the albumin fraction in hemophilia was studied by Feissly (1944). He showed that whereas the coagulation time of whole blood in hemophilia is greatly prolonged, that of the hemophilic "globulin fraction" is only slightly longer than normal. He then showed that hemophilic albumin retards the clotting of both normal and hemophilic "globulin fractions." These experiments, which suggest an increase in the inhibitory system in hemophilia, are supported by the work of Tocantins (1943) who postulates an increase in antithromboplastin.

A direct relationship between a shortening of the coagulation time and fibrinolysis occurs following adrenalin injections. Cannon and Mendenhall (1914 a & b) showed that adrenalin stimulation of the sympathetic nervous system and emotional stimuli lead to a shortening of the coagulation time of recalcified plasma. This hastening of coagulation is apparently not due to any change in prothrombin because Wakin et al (1946) have shown that adrenalin causes no alteration in the Quick prothrombin time. It therefore seems possible that the change in coagulation time may be related to an increase in thromboplastin. Since there is now considerable evidence that thromboplastic action is in part proteolytic, and since adrenalin injections consistently produce fibrinolysis, it seems possible that this shortening of the coagulation time may be related to fibrinolysis.

THE ALARM REACTION OF SELYE

The suggestion that fibrinolysis occurs in all conditions which lead to secretion of adrenalin has interesting implications in relation to Selye's concept of the alarm reaction (Selye 1946 etc.). According to Selye, exposure to any noxious or excessive stimulus is followed by a uniform pattern of pathologic changes. There is an initial shock phase, with the characteristics usually associated with this term, and a succeeding counter shock phase when the phenomena of shock are reversed. The reaction is accompanied by involution of the lymphoid tissue, hypertrophy of the adrenal cortex, and excessive secretion of adrenal cortical hormones.

The marked negative nitrogen balance of the alarm reaction which may be related to plasmin, has been studied in detail following trauma (Cuthbertson 1930, 1932, 1935, Vaughan et al 1947), burns (Cope et al 1943, Taylor et al 1943, Chanutin and Gjessing 1946), operations (Chanutin et al 1938), hemorrhage (Elman 1944), and infections (Coleman and DuBois 1915). There is an extensive loss of nitrogen from the tissues, an immediate and progressive fall in plasma-albumin, and from the second or third day, a rise in plasma-globulin which often continues until the albumin-globulin ratio is reversed. The early fall in plasma-albumin might be due to fibrinolysis initiated by adrenalin. The continuing destruction of protein reserves might be related to the excessive secretion of adrenal cortical hormones which are known to cause mobilization of globulins from the tissues (White and Dougherty 1945). The reversed albumin-globulin ratio thus produced might be associated with an imbalance of the plasmin-antiplasmin complex, causing further catabolism of protein.

Fibrinolysis and Anaphylaxis

Rocha e Silva et al (1946 a, b & c) have suggested that fibrinolysis may play an important part in anaphylaxis. It is well known that intravenous injections of

trypsin cause profound shock (Tagnon 1945) Rochas e Silva and Grana (1946a) showed that trypsin perfused through the isolated liver causes the release of histamine. On the other hand an anaphylactic antigen caused no release of histamine from the livers of sensitized animals unless it was perfused in whole blood. Since anaphylactic shock is associated both with a rise in blood histamine and fibrinolysis (e Silva and Teixeira 1946b) they suggested, that, in contact with sensitized tissue, the anaphylactic antigen releases fibrinolysin which in turn releases histamine from the liver cells. In 1947 Ungar showed that incubation of sensitized tissue with the specific antigen does cause a release of proteolytic enzyme and in 1945 he showed that resistance to trauma was associated with a decreased release of histamine from the cells and an increase in blood antitrypsin. These observations clearly support the original suggestion of Rochas e Silva.

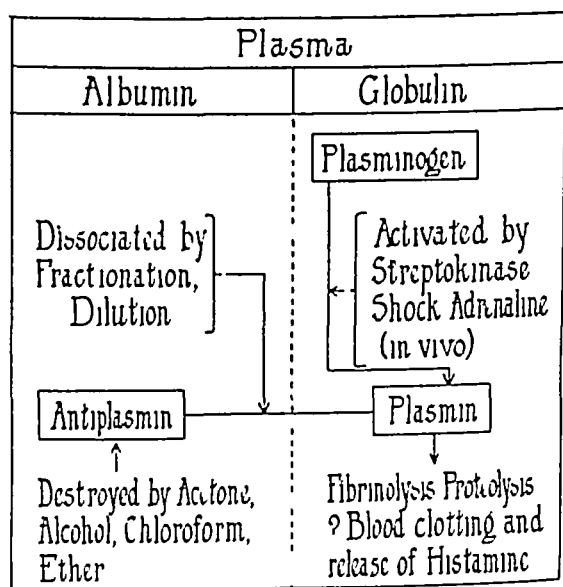

FIG. 4. Diagrammatic representation of the activation of plasmin and its effects.

There is, therefore, cumulative evidence that the plasmin-antiplasmin complex plays a fundamental part in several essential physiologic processes.

CONCLUSIONS

1. There exists in normal blood a proteolytic enzyme "plasmin," its precursor "plasminogen" and its inhibitor "antiplasmin," the latter being in excess.
2. Plasmin and plasminogen are associated with the globulin fraction of the plasma, antipiasmin with the albumin.
3. Plasmin activity can be produced in plasma "in vitro" by the action of streptokinase which activates plasminogen, by chloroform which destroys antipiasmin, or by procedures, such as fractionation of the plasma, which separates the plasmin-antiplasmin complex.
4. Active plasmin will cause fibrinolysis, digestion of the plasma proteins and casein and gelatin.

- 5 Enzymes resembling plasmin have been found in various tissues, particularly lung and in urine
- 6 Inhibitors resembling antiplasmin have also been found in various tissues, particularly the spleen
- 7 Plasmin activity may occur in the living subject following various stimuli, such as trauma, fear, severe exercise, or the injection of adrenalin
- 8 The mechanism of this activation is still obscure, and involves factors not present in whole blood. It can be obtained in the absence of the normal function of the liver, pancreas, spleen and suprarenal cortex
- 9 Such plasmin activity may be concerned in the phenomena of shock, in the equilibrium between protein breakdown and synthesis, in the mechanism of blood coagulation, and in allergic reactions
- 10 The position may be illustrated diagrammatically as shown in figure 4

ACKNOWLEDGMENT

We wish to thank Dr A. H. T. Robb-Smith for his interest and advice, Mr J. Pilling for much work in the laboratory, and Mr Woolf for help with the bibliographical references. The general investigation of fibrinolysis is financed by the Medical Research Council.

HEMORRHAGIC DIATHESIS ASSOCIATED WITH THE PRESENCE OF AN ANTICOAGULANT IN CIRCULATING BLOOD CASE REPORT AND LABORATORY STUDIES

By J P SOULIER, M D , AND M BURSTEIN, M D

THERE ARE three observations of the presence of an anticoagulant in the blood of patients with a hemorrhagic diathesis in the American literature ^{15, 16, 4}

The following case report constitutes the fourth observation of such an occurrence

The patient was studied at the "Hospital des Enfants Malades" by Dr Maurice Lamy, under whose direction this work was carried out

M B, age 21, male, was admitted to the hospital in July, 1946, with a diagnosis of hemophilia. Past history revealed the frequent occurrence of hemorrhagia episodes, the first one occurring at 1½ years of age. There were oral, nasal, and gastro intestinal hemorrhages, but most episodes were articular, and occurred in the absence of any significant trauma. These hemorrhages required blood transfusions on two occasions.

Joint hemorrhages were particularly frequent, repeating themselves 5 to 6 times in a year. They affected mostly the elbows, knees, and ankle. When seen, the patient was confined to bed for the last 2 months with involvement of both knees and hematuria.

The family history is not contributory. He was the only child and his mother died of tuberculosis. The maternal grandmother, her children and grandchildren were always in good health. The paternal grandfather was healthy. His father had frequent episodes of epistaxis.

Physical examination revealed a pronounced muscular atrophy, affecting the inferior limbs mainly, a hemophilic arthritis, and a malformation of the uvula. No hematomas in the muscle. The remainder of the physical examination was normal. There was no syphilis.

The blood coagulation time was 6 hours (at 37°C), the bleeding time 4 minutes. The red cells count was 4.1 million with a hemoglobin of 75 per cent.

The leukocyte count was 9,800 with the following differential count: neutrophils, 76 per cent, eosinophiles, 2 per cent, lymphocytes, 16 per cent, monocytes, 6 per cent.

On Aug. 2, 1946, the patient received a transfusion of 300 cc of blood (fresh). The following day, the clotting time was still 6 hours. The patient was sent home where he was treated with distilbestrol. He was readmitted Oct. 31. In the interval period he had no severe hemorrhage episodes. There were a few ecchymoses and gingivorragia. The clotting time was 4½ hours and the bleeding time 17 minutes. The tourniquet test was negative and the capillary resistance measured by the cuff method was found normal (no petechiae after 6 minutes under a pressure of 90 mm of mercury). Examination of the blood gives the following results: Red Cells, 5.1 millions, Hemoglobin, 15 g. 3, Hematocrit, 50, MCV, 97.3 µ, White Cells, 6,400, Platelets, 300,000 of which 90 per cent were round forms, Fibrinogen, 400 mg per 100 cc, Calcium, 9.9 mg per 100 µ.

The purpose of this communication is to report the different studies carried out on the blood of this patient. The blood was obtained from the antecubital vein with and without anticoagulant. The anticoagulant used was a 4 per cent solution of sodium citrate, 1 cc of which was used for every 9 cc of blood. Plasma was obtained by centrifuging.

From the Centre National de Transfusion Sanguine et de Recherches Hématologiques, Paris.
This case is the subject of a report under the title "Sur un anticoagulant présent dans le sang d'un sujet se présentant cliniquement comme un hémophile" by M. Lamy, M. Burstein and J. P. Soulier, to be published in the Rev. d'Hématologie.

1 Anticoagulant action of noncitratd plasma on normal whole blood

Blood was obtained from the patient without anticoagulant. The red cells were allowed to sediment for 3 hours, and the supernatant plasma separated. Increasing quantities of this plasma were added to 1 cc of normal human blood. Table 1 shows that the patient's blood plasma had a marked anticlotting effect on normal blood.

TABLE 1—Clotting Time of 1 cc of Normal Blood to Which the Patient's Plasma Was Added (Experiment Done on Nov. 14, 1946) To 57 C Test Tubes 13 x 110 Duplicate Readings

Patient's plasma cc	Normal blood #1 (1 cc) Clotting time (minutes)		Normal Blood #2 (1 cc) Clotting time (minutes)	
0	8	10	10	15
0.1	26	33	45	48
0.2	120	180

0.1	1.9	17
0.1	0.9	35
0.1	0.4	60
0.1	0	240+

TABLE 3—Howell's Time of Patient's Citrated Platelet-free and Platelet with Plasma (0.2 cc plasma plus 0.2 cc CaCl_2)

Date	Number of platelets (per mm ³)	Clotting time (minutes 1)	Type of plasma
11-7-46	115,600	32	Platelet rich
	225	360+	Platelet free
11-14-46	125,000	45	Platelet rich
	340	360+	Platelet free

2 Anticoagulant action of citrated plasma from the patient's blood on citrated plasma from normal blood

Citrated normal plasma was obtained by spinning citrated normal blood at 6,000 rpm for 30 minutes. Increasing quantities of this plasma were added to a fixed quantity of citrated platelet-free plasma from the patient's blood. Recalcification of the mixture was done by adding an equal volume of 0.025N CaCl_2 and the clotting time (Howell's time) measured. Table 2 shows a typical experiment performed on Sept. 14, 1946. The results can be explained only by the presence of an anticoagulant in the patient's plasma.

3 Clotting time on recalcification (Howell's time)

a Effect of platelets on Howell's time

Platelet-rich citrated plasma was obtained by spinning citrated blood at 2000 rpm for 3 minutes. Platelet-free plasma was prepared by spinning the platelet-rich plasma at 6000 rpm for 30 minutes, and passing the supernate through an Iena #4 filter. The filtrate was platelet-free for all practical purposes. Table 3 shows the results obtained by recalcifying both plasmas. The Howell's time was considerably prolonged when the platelets were removed. Similar results were obtained by Quick with hemophilic plasma. It is noticeable that the Howell's time of this patient's plasma, devoid of platelets, approximated very closely the clotting time of whole blood. However, the clotting time of platelet-rich recalcified citrated plasma was much shorter, which may indicate the existence of a destruction of the platelets during recalcification and liberation of thromboplastin from the platelets.

b Effect of destruction of platelets on Howell's time

It is well known that the clotting time of citrated recalcified plasma (Howell's

TABLE 4—*Howell's Time before and after Destruction of Platelets*

Date	Clotting time of recalcified citrated platelet rich plasma from patient's blood (Minutes)		
	Intact platelets	Platelets destroyed by freezing	Platelets destroyed by adding distilled water
7-25-46	90	10	15
8- 1-46	90	12	15
8- 3-46	100	20	
11- 7-46	32	20	22
11-14-46	45	13	14

time) is shortened if the platelets are destroyed and allowed to release their thromboplastin—according to Tzanek and Burstein² citrated plasma clots faster if, before recalcification, it is frozen and then thawed. They found that this procedure shortened the clotting time of citrated recalcified plasma from 3–6 minutes to $1\frac{1}{2}$ – $2\frac{1}{2}$ minutes. One can also destroy the platelets by the addition of 3 volumes of distilled water to one volume of citrated plasma. Iso-osmoticity is then re-established by adding one volume of a 3.6 per cent solution of sodium chloride. We have studied the effect of the destruction of platelets on the Howell's time of citrated platelet-rich plasma from the patient's blood.

Table 4 shows that there is a considerable shortening of the clotting time after destruction of the platelets. However, this clotting time is still abnormally prolonged.

Control experiments on platelet free plasma showed no effect of freezing on the clotting time. However, the addition of distilled water to the platelet free plasma resulted in a shortening of the clotting time. This effect may be due to dilution of the anticoagulant by the distilled water since the addition of saline instead of distilled water produced a similar effect.

c Effect of dilution on Howell's time

The effect of dilution was studied platelet free citrated plasma from the patient's blood was diluted with saline and then recalcified and the clotting time at 37 C noted

Table 5 shows that dilution shortens the clotting time

4 Effect of concentration of calcium on Howell's time

Lozner, Joliffe, and Taylor¹⁵ state that the addition of calcium to whole blood obtained from their patient produced a shortening of the clotting time We have not observed any effect in the case reported here from the addition of concentrations of calcium chloride between 0.05N and 0.0125N

5 Effect of storage of plasma on Howell's time

When the patient's citrated plasma was kept at room temperature for 48 hours, the Howell's time was not modified provided the plasma was devoid of platelets

6 Effect of normal plasma and fractions of normal plasma on the clotting defect of the patient's plasma

TABLE 5 — *Effect of Dilution on Howell's Time*

Date	Howell's time of undiluted plasma (minutes)	Howell's time of diluted plasma (0.2 cc plasma + 0.8 cc physiological saline) (Minutes)
7-25-46	360	40
3- 1-46	360	40
11- 7-46	300	90
11-14-46	300	90

We have used normal human plasma and one of the plasma fractions obtained by Cohn and his coworkers in the department of Physical Chemistry of Harvard Medical School * The plasma fraction used was Fraction I of Cohn, which in addition to fibrinogen contains most of the antihemophilic activity of normal plasma Two types of fraction I were used One from normal human plasma, and the other from hemophilic blood plasma † These fractions were obtained as a dry powder 40 mg of which was dissolved in 2 cc physiologic saline at pH 7.5

Table 6 shows that neither type of fraction I in the quantities used in this experiment had any effect on the clotting defect of the patient's plasma

7 Quick's prothrombin time of the patient's plasma

This was determined by means of brain's thromboplastin the prothrombin time of the patient's plasma determined by this method was 20 seconds, very near the prothrombin time of the normal control (table 7) However, with smaller amounts of thromboplastin there appears a widening divergence between the patient's plasma and the normal control (table 7)

* Obtained through the courtesy of Dr. E. J. Cohn

† Obtained through the courtesy of Dr. F. H. L. Taylor

8 Effect of thrombin on citrated plasma absence of immediate antithrombin

The preparation used was obtained from the Roussel's laboratories as a dry powder, 50 mg of which assayed 12 Iowa units. Fifty milligrams was dissolved in 2 cc of physiologic saline. At all dilutions used (table 8), it was impossible to detect a significant immediate antithrombotic action in the patient's plasma.

1/32	228	270

9 Progressive antithrombin

Normal serum or plasma contain an antithrombin which is called 'progressive' because it inactivates thrombin when incubated with thrombin. Table 9 shows that the patient's plasma did not inactivate thrombin more actively than did normal plasma and did not therefore contain more progressive antithrombin than did normal plasma.

10 Antifibrinolytic activity of the plasma

It was decided to test this activity in the patient's plasma because there are similarities between the trypsin inhibitor from soya bean, and the anticoagulant

present in the patient's plasma Both substances are ant clotting but not anti-thrombic They both are thermostable It became necessary to investigate whether the patient's plasma exhibited enhanced antiproteolytic or antifibrinolytic activity

TABLE 9—*Effect of Incubation of Patient's Plasma with Thrombin Thrombin Added to Defibrinated Plasma, the Mixture Incubated 15 Minutes at 37 C and the Clotting Time on Fibrinogen Measured at 37 C Defibrination Was Done by Heating at 56 C for 5 Minutes*

As a source of fibrinolysin, we used a preparation of chloroform plasma (Nolf-Tagnon) The fibrinolysin preparation was added to citrated plasma and a clot was obtained by the addition of thrombin The disappearance of the clot was taken as a measure of the intensity of the fibrinolysis

11 Finally we have observed that the quantity of anticoagulant agent in the patient's plasma increased from August to November 1946. This is shown by the fact that in August a mixture of 1 volume of citrated normal plasma and 1 volume of citrated patient's plasma, after addition of calcium, clotted in 50 to 60 minutes, while in November, in order to obtain the same clotting time, it was necessary to add 4 volumes of normal plasma to one volume of the patient's plasma. It is difficult to say at the present, whether this increase was the result of the transfusion of blood, as was the case in the patient described by Munro.¹⁷

DISCUSSION

The patient discussed in this communication was clinically a hemophiliac. This diagnosis was based on a prolonged clotting time, a normal bleeding time, and the occurrence of hemorrhagic episodes and joint hemorrhages. The disease started at the age of 18 months. However, certain aspects of the case were not in agreement with the diagnosis of hemophilia among which the absence of a family history of the disease and the lack of effect of blood transfusions. Also, atypical were the lack of effect of the addition of either normal plasma or fraction I of Cohn on the clotting time in vitro of the patient's blood. Finally, and contrary to what occurs in true hemophilia, the blood or plasma from the patient had a definite anticlotting effect on normal blood or plasma.

There is little doubt that the blood of this patient contained a circulating anticoagulant. Munro^{4, 5} has reported a similar occurrence in a patient classified as hemophilic. In Munro's case, the appearance of the anticoagulant followed the use of repeated blood transfusions. In the case reported here, such an etiology seems unlikely in view of the fact that the patient had received one single transfusion before the time that the circulating anticoagulant was observed in his blood. This single transfusion was given him when he was a child. Later transfusions, given after the circulating coagulant was observed, had no effect on the clotting time or, if they had any effect, it was in the direction of *prolonging* the clotting time, although this prolonging effect was difficult to demonstrate since the blood, before transfusion, clotted in the very long time of 6 hours at 37° C. We have given this patient one transfusion only because of the detrimental effect of this treatment in this type of cases, as described by Munro.¹⁷

The anticoagulant present in the plasma of this patient is thermostable. We were able to heat the plasma at 65° C. for 30 minutes without causing the disappearance of the anticlotting activity. At ice box temperature the activity is maintained for 8 days at least. At room temperature, the activity decreases after 48 hours. The anticoagulant appears not to be identical with heparin since we have observed no neutralizing effect from the addition of toluidine blue. Furthermore, quantities of protamine between 0.001 mg. and 0.1 mg. for 1 cc. of plasma did not affect the clotting time.

The anticoagulant was not an antithrombin and did not appear to be antithrombolytic. The prothrombin time determined by the method of Quick was not significantly altered.

Concerning the mechanism of action of the anticoagulant, one can say that this

principle acts on the first phase of the coagulation phenomenon since we have shown that it is not antithrombin. It would appear therefore that it opposes the transformation of prothrombin into thrombin.

The anticoagulant could conceivably oppose this transformation by one of three possible mechanisms (1) by an action on calcium that this was not the case is affected by the fact that the blood calcium was normal and that varying the amount of calcium did not correct the prolonged clotting time, (2) by an action on prothrombin this seems unlikely since the prothrombin time was normal, on the other hand we have mixed 0.1 cc of the patient's plasma with 1 cc of prothrombin poor plasma (obtained from a patient treated with dicumarol) containing 33 per cent of the normal level of prothrombin. The clotting time of the mixture (38-48 minutes) was found to be similar to that of a control (38-45 minutes), (3) by an action on thromboplastin this is rendered unlikely by the fact that small quantities of thromboplastin added to the patient's plasma corrected the clotting defect quite completely. The antithromboplastin described by Tocantins,⁶ in contrast to the anticoagulant described here, is destroyed by heating at 50 C.

Other hypotheses should be briefly considered. According to Lenggenhager,⁷ the thromboplastin originating from platelets exists as a prothromboplastin and is activated by contact with foreign surfaces and calcium, while the thromboplastin derived from cellular material exists in an active form. According to this hypothesis, the anticoagulant described here could conceivably work by opposing the activation of the prothromboplastin.

According to Nolf,⁸ Howell,⁹ Patek and Stetson,¹⁰ Patek and Taylor,¹¹ Feissly,¹² Bendien and Van Creveld,¹³ blood plasma contains an essential factor of blood coagulation distinct from prothrombin. This factor exists in plasma as an inactive precursor. It is thermolabile and is bound to the englobulin fraction of plasma. It is called antihemophilic factor, globulin substance, plasma thromboplastin, etc.

According to Frederica,¹⁴ and, independently, to Ferguson,¹⁸ the plasma tryptase is probably the active principle which in association with calcium and the platelets activates prothrombin. This author thinks that component A of prothrombin, described by Quick,¹ is identical with the plasma tryptase.

A definite explanation of this mechanism of action of the anticoagulant described here must await a better understanding of the mechanism of normal coagulation itself. Our impression is that this anticoagulant acts on either the mechanism of activation of prothromboplastin, or the antihemophilic substance, or the plasma tryptase.

An interesting question is whether our anticoagulant is identical with the anti-clotting substances described in 3 different publications.^{15 16 4} Certain common features suggest an identity: these are the thermostability, lack of antithrombin action, lack of action on the prothrombin time.

The substance described by Munro^{4 17} appears to be a γ globulin.

SUMMARY

A new observation of a hemorrhagic diathesis associated with the presence of an anticoagulant in the circulating blood is reported here. The patient was a 21

year old male, appearing by clinical evaluation to have hemophilia, but without a family history of hemophilia. The blood and plasma were strongly anticlotting and had a very long clotting time. The clotting time of recalcified citrated plasma was greatly delayed by removing the platelets. Freezing and thawing of platelet-rich plasma resulted in a marked shortening of the clotting time. Dilution of the plasma shortened the clotting time, while the addition of calcium and storage of the plasma had no effect.

The prolonged clotting time was not corrected by the addition of normal plasma or plasma fractions having antihemophilic activity. The prothrombin time was nearly normal. Small quantities of thromboplastin were very effective in shortening the clotting time. The anticoagulant had no antithrombin activity. The "progressive" antithrombin and antifibrinolysin of the patient's plasma were normal.

The anticoagulant acts during the first phase of coagulation by inhibiting an (plasma) activator of prothrombin. It appears to be identical with the anticoagulant described in three previous publications from the United States.

THE RELATIONSHIP BETWEEN HEPARIN DOSAGE AND CLOTTING TIME

By L. B. JAKES, M. A., PH. D., AND ANN G. RICKER, M. A.

THE GREAT interest of Dr. Minot in all branches of hematology has always included an appreciation of the problems involving the anticoagulants. The recent development of anticoagulant therapy has increased this interest. We therefore are pleased to present as an indication of our esteem a recent study of factors affecting the action of heparin *in vivo*. We believe that a study of this nature is of value in leading to an understanding of the various physiologic factors involved in this action and hence to an appreciation of the principles involved in its administration.

Heparin when used experimentally or clinically is usually controlled by the determination of the prolonged clotting time produced. It was shown in a previous paper¹ that the value of the clotting time produced will depend on both the coagulant power of the blood and the ability of the body to remove heparin from the circulation. Crafoord² reported that the blood became more resistant to the action of heparin after operation, suggesting an increase in coagulability. Following this lead, De Takats,³ Waugh and Ruddick,⁴ and Whittaker⁵ have suggested tests of blood coagulability based on the resistance of the blood to the anticoagulant power of heparin. In a continuation of the previous study, further observations of the effect of heparin dosage on the clotting time in the dog have been made. These observations give a clearer concept of the factors involved both in the use of heparin as a test of the clotting function of the blood and also in its administration.

METHODS

Dogs of 10 to 20 Kg. body weight were used. The experiments were conducted on trained, unanesthetized animals unless otherwise indicated. Unless otherwise stated, blood samples were taken by venous puncture from superficial veins through the skin. Care was taken to ensure that the sample was taken expeditiously without trauma. The syringe and needle were first rinsed with saline and emptied of air, saline being left in the needle. Normally, 2 cc. of blood were taken and the first 0.5 cc. and last 0.5 cc. of blood were discarded. If larger quantities of blood were required the same technic was used, larger amounts of the first and last of the sample being discarded. Clotting times were determined at 37°C. in the coagulometer described by Murray, Jakes, Perrett and Best.⁶

We are indebted to the Connaught Medical Research Laboratories, University of Toronto, for a generous supply of heparin. This was received as a solution of 1000 Connaught units/cc. (90 mg. per cc.) of the sodium salt of beef heparin. The unit is the anticoagulant activity of 1/100 mg. of the crystalline barium salt as prepared by the method of Charles and Scott.⁷ This unit is as closely as one can ascertain, the same as the provisional International Unit⁸ which is expected to replace it, and also the original unit used by Howell. In these studies the heparin was injected intravenously.

CLOTTING TIME RESPONSE TO HEPARIN *IN VITRO*

When the clotting time is determined with varying amounts of heparin added to the blood *in vitro*, a curve such as that of *a* in figure 1 is obtained. The practical

From the Departments of Physiology, University of Toronto, Toronto, and the University of Saskatchewan, Saskatoon, Canada.

significance of this curve is that a certain level of heparin is required before there is any significant effect on clotting time, whereas increases in heparin concentration beyond this value result in the clotting time being very markedly increased for slight increases in heparin concentration. Several empirical equations have been suggested for this curve.^{1 9 10} However, a simple procedure is to plot the data on semilogarithmic paper, whereupon a straight line is obtained. In figure 1 this has been done to give curve *b*. The same procedure has previously been recommended for the relation between thrombin concentration and clotting time¹¹ and appears to be a consequence of the determination of clotting times, since a similar

FIG. 1 Effect of heparin concentration in vitro on clotting time. Blood samples taken from the exposed femoral vein and 1 cc. added to the quantities of heparin shown.

logarithmic relation can be obtained for many coagulant and anticoagulant substances.

It would appear of practical importance to have some single value to express the sensitivity of a blood sample to the anticoagulant action of heparin. This is easily achieved by taking the slope of the straight line obtained on semilog paper. This gives us the "heparin sensitivity value," and is calculated from $\frac{\log T_2 - \log T_1}{c_2 - c_1}$, where T_2, T_1 = clotting times and c_2, c_1 = heparin concentrations at two points on the line. Since the coagulometer used measures clotting times to the nearest minute only, the greatest error was on the normal clotting time. Hence, the line

was drawn to give the best fit for all the points, without necessarily passing through the normal value. Typical results obtained in a series of 15 dogs are shown in table 1. The clotting times as those in figure 1 were determined on blood removed from an exposed femoral vein. It can be seen that the range for the heparin sensitivity values for the animals was from 0.50 to 48.8. These extreme values were for only two animals, representing the hyperreactors and hyporeactors of De Takats. The values for 50 per cent of the animals were in the range 2.3 to 3.2, while 5 (33 per cent) were moderate hyperreactors giving values of 3.8 to 7.6. The difference between different animals with regard to their sensitivity to heparin is a relatively permanent difference. Determinations on the same animal, 10 days apart, shown in table 2, give sensitivity values agreeing to within 10 per cent, while the

difference between the average normal dog and the hyperreactors is one of several hundred per cent.

Another method of measuring sensitivity to heparin, although by no means as informative, is to report the clotting time for a single dose of heparin. This has been done in table 1 for 0.1 and 0.5 units of heparin/cc. Also reported is the normal or control clotting time, i.e., the clotting time without added heparin. The value of the clotting time for 0.1 units of heparin was from 1.7 minutes (almost the same as the normal) to over 24 hours. The median value was 4.7 minutes. Another way of giving the values is the concentration of heparin required to double the normal clotting time. This was 0.008 units for dog A-21, and 0.6 units for dog A-20, the median value for the series was 0.11 units. There appeared to be no correlation be-

tween the normal clotting time and sensitivity to heparin. Both hyper- and hyporeactors were found with normal clotting times longer than the average value.

The sensitivity of blood to the anticoagulant action of heparin depends (1) on the individual from whom the blood is taken, and (2) on the technic used both for removal of the blood and for determination of the clotting time. In the experiments reported in table 1, the dogs were under an anesthetic and the blood samples were taken from the exposed femoral vein. Direct experiments showed that this procedure increased the sensitivity of the blood sample to heparin. In a later series, reported in table 2, the blood was taken by the usual venipuncture procedure through the skin. The decrease in heparin sensitivity is shown by the decrease in the sensitivity value to the level 0.8–1.4, the median being 1.03, or a clotting time of 12.1 minutes for 0.5 units. Hyper- and hyporeactors were not used for this series. The series again demonstrates the individual variation even in a series of animals selected with regard to their response to heparin. Likewise, there is no indication from the normal clotting time of their response to heparin.

The above demonstrates one factor which can change the sensitivity of the blood sample for heparin. Other factors which can change this are the use of saline to moisten the syringe, removal of the needle before transferring the blood to the tube for the determination, surface coatings, etc. Finally the temperature at which the determination of clotting time is conducted markedly affects the sensitivity of the sample. Heparin shows least anticoagulant activity at 20–25°C, its activity increasing above and below this temperature range.

While the great variation in the response of the clotting time to heparin due to changes in technic of venipuncture and determination of clotting times might suggest that the use of clotting times should be discarded as far as heparin is concerned, actually the value of such determinations is greatly increased when these factors are appreciated and utilized. As can be seen from figure 1, the relation between the clotting time and heparin concentration is such that measurable changes in clotting time can be obtained only over a rather narrow range of concentrations, a considerable handicap in experimental studies on heparin. However, by suitably modifying the method, it is possible for any desired range of heparin concentration within reason to be made measurable. With proper control of these technical factors, satisfactory reproducible results are obtainable with any given method.

In using heparin both experimentally and clinically, it would appear advisable to administer it on a weight or potency basis (i.e., in milligrams or units per kilogram) rather than on the basis of an arbitrary clotting time. Since the same dosage is not necessarily required for all uses, the dosage can be modified to the particular use. It follows from the above discussion that the method for the determination of clotting time, used to determine the duration of heparin action in the circulation as discussed below, may be suitably modified to give measurable clotting times at this dosage level. While the dosage for a particular purpose may be established for the average individual, it may be advisable to modify it for those individuals whose blood proves to be either highly sensitive or relatively insensitive to the anticoagulant action of heparin.

THE CLOTTING TIME RESPONSE TO HEPARIN IN VIVO

As first reported by Howell,¹² a single intravenous injection of heparin is followed by a rapid rise in the clotting time, and then by a more gradual but still rapid decrease to the normal value. As seen from the relationship between heparin concentration and clotting time in vitro, the rapid changes in clotting time at the higher values are due to the nature of the relationship between heparin concentration and clotting time. Hence they do not reflect actual changes in heparin concentration in the blood, and in order to use the clotting time to follow changes in heparin concentration in the blood it is advisable to plot the data, as with the in vitro curves, on semilog paper. When this is done, as in figure 2, it can be seen that

FIG. 2. Effect of heparin in vivo on clotting time. Single intravenous injection of $30 \mu/\text{Kg}$ given at zero time.

the anticoagulant effect of heparin disappears from the circulation in a relatively linear fashion, at the concentration given by this dosage of heparin.

In studying the clotting time response of the animal to injected heparin (fig. 2) three different values are of interest. These are (1) the time required for the clotting time to reach its peak value, (2) the maximum clotting time reached, and (3) the time required for the clotting time to return to normal, or the duration of the hypocoagulable effect. These three values will be considered separately.

Time required for the clotting time to reach its peak value. In figure 2, with a dose of 30 units Kg , the maximum clotting time was reached in four minutes. With a circulation time of 20 seconds, one would expect that the heparin would have exerted its maximum effect within one minute after the injection. Actually, with larger

doses of 100 units/Kg, one usually finds that a ten to fifteen minute period is necessary for the clotting time to reach the peak value. It is evident from this that the delay in developing the hypocoagulability of the blood following the injection of heparin is not due simply to the time required for mixing with the blood. As discussed later, an explanation of this delay has been found. It also should be pointed out that this effect is observed only with doses of heparin which give clotting times that are still measurable. With very large doses (1000 units/Kg) complete incoagulability develops immediately.

De Takats⁷ has reported that the clotting time response to injected heparin is biphasic. He noted a rise to the maximum within one minute of injection. This was followed by an immediate return to the normal value which was then followed by the rise in clotting time usually observed. No evidence of such a biphasic response is observable in the data reported in figure 2 nor have we observed any evidence of this in a series of dogs in which samples were taken for clotting times every minute after injection. De Takats' results were obtained on man. However, it is difficult to deduce any rational basis for such a phenomenon, since, as shown below, there is essential, even though not complete, quantitative agreement between the clotting times obtained when the heparin is mixed with the blood *in vivo* and *in vitro*.

The maximum clotting time. It was concluded previously that the maximum clotting time obtained on the injection of heparin was the same as if a corresponding amount of heparin were mixed with the blood sample *in vitro*. In the present investigation a more exact test of this hypothesis was conducted, using the present methods. In each case the effect of heparin concentration on clotting time was first determined *in vitro* by adding blood samples to various concentrations of heparin. The results were then plotted on semilog paper to give a straight line and the slope of the line (heparin sensitivity value) is reported in the table. Thirty or 100 units/Kg were then injected and the clotting time determined at frequent intervals, as in figure 2. In table 2 is shown the maximum clotting times obtained for the injections. The clotting time for the same concentration of heparin added to the blood *in vitro* was determined from the *in vitro* experiment, the blood volume being taken as $1/11$ th of the body weight. This is likewise reported as the peak clotting time (*in vitro*). It can be seen that of fifteen injections the clotting time *in vivo* was always much greater than that obtained *in vitro*, the value obtained from mixing *in vivo* being three to ten-fold that *in vitro*.

The only difference between the two series is that in the one case the heparin mixed in the body is in contact with the blood for the five to ten minutes required for the clotting time to rise to the maximum. Quick¹³ has reported that heparin shows an enhanced activity on incubation with an oxalated plasma system. In order to test the effect on heparin activity of incubation with blood, 10 cc of blood was drawn into 10 cc of sodium oxalate solution. One cubic centimeter of oxalated blood was then added to each of a series of tubes containing 0, 0.1, 0.25 and 0.5 units of heparin and the tubes were allowed to stand thirty minutes at 25°C. The tubes were then placed in the coagulometer, equivalent calcium was added and the clotting time was recorded. A control series of tubes was set up similarly, but the

heparin was added at the end of the thirty-minute period before the addition of calcium

The results for several animals are shown in experiments 1 and 2, of table 3. It is evident that after incubation with heparin the clotting times of the samples are much longer. In order to avoid the decalcification, the experiment was also conducted in another way. It has previously been shown by Jaques, Fidler, Feldsted and Macdonald¹⁴ that coating glassware and needles with the silicone "Dri-Film"

gives a surface which is apparently inert to the clotting system and that, provided the blood sample is taken in such a way as to prevent contamination with damaged tissue, such blood does not clot for several hours. Five cubic centimeters of blood were removed from a superficial vein with a silicone-coated syringe and needle. The first and final 0.5 cc of blood were discarded and 1 cc portions of blood added to varying amounts of heparin in silicone-treated tubes. These were allowed to stand 10 minutes at 37 C. The samples were then transferred with an untreated syringe

and needle to the coagulometer and the clotting times were recorded. The values are shown in experiments 3, 4, 5 and 6, table 3, opposite I. The control tubes in experiments 3 and 4 were set up identically and the heparinized blood then transferred to the coagulometer immediately without incubation. In experiments 5 and 6 the control blood was added to the silicone tubes, incubated ten minutes, and then added to the heparin in the coagulometer tubes.

It can be seen that, irrespective of changes in the clotting time of the blood following incubation (zero heparin), there is a marked increase in the clotting time of the heparinized samples. This result was obtained consistently, with marked differences in technic and in the coagulability of the blood of the individual animal. Evidently a certain period of time is required for heparin to combine with the com-

ponents of the clotting system before it can exert its maximum anticoagulant effect. It appears reasonable to attribute to this factor both the discrepancy between the clotting times obtained on mixing the heparin with the blood *in vitro* and *in vivo*, and also the lag in the rise of the clotting time to its maximum. A great excess of heparin would accelerate the combination of heparin with the necessary factors of the clotting system, and thus cause the disappearance of the lag. As reported above, it was actually found experimentally, that the lag phase disappeared with large doses of heparin.

Duration of the hypocoagulability after heparin injections. The duration of hypocoagulability represents the time during which the anticoagulant activity of heparin remains in the circulation. Reed¹⁵ reported that this time was directly proportional

to the dosage. In the previous study by Jaques¹ this was confirmed, for when the dosage was divided by the time, the ratio obtained was approximately constant and was independent of the dosage level and of variations in individual animals. The value obtained was 2.0 units/Kg./min. Shown in table 2 is the duration of the hypocoagulability for a series of animals receiving injections of 30 and 100 units/Kg. In the present series, likewise, the ratio is constant. The agreement is in fact considerably better than previously, but the average value is 0.9 units/Kg./min. Such a discrepancy is much too great to be due to experimental errors and merits further consideration.

Several factors were different in the two studies. First, crude heparin (15 units/mg) was used in the first series, while all later experiments were conducted with pure heparin. Direct comparison of crude and pure heparin, however, showed no difference in the clotting time response elicited. Secondly, a series of doses (from 31 to 667 units/Kg.) were used in the previous experiments, while only two dosage levels (30 and 100 units/Kg.) were used in the present series. It is significant that in the previous study the values of the ratio for the 31 and 113 unit doses were 1.2 and 1.6 respectively, compared with values of 1.9 to 3.4 (average 2.5) for doses of 200 units/Kg. and over. This result suggests that the value of the ratio changes with the dosage level of heparin. Thirdly, the clotting times were previously determined by the Lee and White method at 25°C, with blood samples taken from the superficial vein through the skin, and it was found that this method failed to detect heparin in concentrations in the blood lower than 0.3 units/cc. On the other hand, the present method detects concentrations of heparin as low as 0.10 units. Hence, at the time when the clotting time was normal by the first method, heparin was still present to give a prolonged clotting time by the second method, thus decreasing the ratio. This factor appears to increase in importance with increasing sensitivity of the clotting time method used to detect the heparin. Thus Jaques, Charles and Best¹⁶ reported data for the injection of 35 units/Kg. in dogs. The clotting time was determined with the coagulometer, but blood samples were obtained from the exposed femoral vein, thus further increasing the sensitivity. In their data, the hypocoagulability lasted from 40 to 80 minutes, again providing a further discrepancy on comparison with the data reported in table 2. However, this effect on this ratio of increasing the sensitivity of the test method for heparin could be predicted from the results reported by Jaques,¹ of the effect on the clotting time of continuous injections of heparin. He found that the rate of disappearance of heparin from the blood at blood levels below 1 unit per cc. was a function of the blood level, so that increasing the sensitivity of the test would result in the detection of heparin in the blood for a relatively much longer time. He likewise reported that at blood levels greater than about 1.5 units per cc., the heparin disappeared from the blood at a relatively constant rate. This, of course, would result in an apparent proportionality between dosage and duration of hypocoagulability, if the time during which blood levels below 1.5 units per cc. could be detected were small in comparison with the total period of hypocoagulability.

It is evident then that the constancy of the ratio of dosage to the duration of

hypocoagulability is more apparent than real. However, the ratio may have some value when used in a strictly empirical manner.

THE COMBINED HEPARIN SENSITIVITY TEST

Waugh and Ruddick⁴ have recently described a test for changes in the coagulability of the blood based on the effect of heparin on the clotting time when added *in vitro*. De Takats' test,⁵ on the other hand, is based on the response when the heparin is injected. Such tests are of value both as a possible indication of suspected thrombotic tendencies and as an indication of the dosage of heparin required. The *in vivo* test as suggested by De Takats is essentially a 'heparin tolerance curve'. As is evident from the previous discussion, this tolerance curve is established by two separate groups of factors. The first is the coagulability of the blood itself. This will determine both the value of the maximum clotting time and also at what level of heparin concentration in the blood it will be no longer possible to determine the residual heparin present by means of clotting time determinations. The second factor consists of those processes whereby the heparin activity disappears from the circulation.

It would appear of value, in studies on heparin at least, to use a test which distinguishes between and tests both of these factors. This can be done by determining the response of the individual to heparin added to the blood both *in vitro* and *in vivo*. By thus using both types of response we can obtain a maximum amount of information regarding these systems. Unfortunately, the incubation effect described above, which is effective *in vivo*, forbids the direct quantitative application *in vivo* of the data obtained in the '*in vitro*' test. Variations in the rate of reaction of heparin with the clotting factors (the so-called incubation effect) can probably be determined by inspection of the initial portion of the *in vivo* curve, however. Finally, the value of both tests, and the information obtained from them, can be greatly increased by suitable plotting on semilog paper to give linear relationships. In this way it is possible to obtain the maximum information from the few points which practical considerations allow one to determine.

In our laboratory the test is actually conducted as follows: 0, 0.2, 0.5 and 1.0 units of heparin in 0.3 cc. of saline are taken in tubes in the coagulometer. Five cubic centimeters of blood is drawn, as described under *Methods*, and 1.0 cc. is added to each tube, the first and last portions of blood being discarded. The clotting times of these samples are determined, establishing the *in vitro* curve. Thirty units/kg. of heparin are then injected intravenously and the clotting time determined at five to ten minute intervals. This is usually repeated with a 100 units/kg. dose, to give two *in vivo* curves. Typical results are shown in figures 3 and 4. It is our impression that the first blood sample taken from an individual animal has a longer clotting time than do subsequent samples. We therefore prefer to use this for other purposes or discard it when conducting clotting studies.

The effect of anesthesia on the clotting time response to heparin. It has long been known that anesthetics affect the clotting time. It was necessary, therefore, to examine their effect on the test. A series of dogs, after repeated testing, were anesthetized and the response again determined. The effect of a barbiturate (sodium pentobar-

bital) is shown in figure 3. This anesthetic was given intravenously. It can be seen that pentobarbital definitely increased the clotting time response. This effect was relatively greatest, however, on the normal clotting time (without heparin) indicating a decrease in the coagulability of the clotting system. This was evidently relatively independent of the action of heparin, since the two lines converged. It can also be seen that the difference in the response *in vivo* after this anesthetic can be explained on the basis of this change in the coagulability of the blood.

Four dogs were tested for their sensitivity to heparin during anesthesia with ether by inhalation with the open mask method. The results of these experiments were somewhat contradictory and did not show the reproducibility in the response

FIG 3 Effect of anesthesia with sodium pentobarbital on the heparin sensitivity test. Left-hand figure is for the *in vitro* test, right-hand figure for the *in vivo* test. —x— normal unanesthetized animal. —●— same animal under pentobarbital anesthesia.

seen with the barbiturate anesthesia and the nephrectomy experiments to be discussed later. Two dogs showed no change in clotting time with ether, one showed an increase, the other a decrease. Three of the four dogs showed a definite increase in sensitivity to heparin *in vitro*. In all four dogs there was fairly close agreement in the response *in vivo* with and without the anesthetic. It has been suggested that the effect of ether anesthesia on clotting is due to the liberation of adrenaline. This would explain the variability in response as judged by the heparin test. Two dogs were anesthetized with urethane. There was no change in clotting time of the animals but a definite decrease in heparin sensitivity. There was no change in the *in vivo* response.

It is evident from the above that the test is affected by anesthetics. The var-

ability under ether indicates that caution must be exercised in applying the test with this anesthetic. However, the use of the test is possible following anesthesia with pentobarbital.

The effect of treatment with india ink on heparin sensitivity Various investigators have suggested a relationship between heparin and the reticulo-endothelial system. Godlowski¹⁷ originally reported that the injection of heparin resulted in a blockage of the activity of the reticulo-endothelial system as judged by the uptake of india ink. Rigdon¹⁸ has recently completely failed to confirm this. On the other hand, Knisely, Bloch, and Warner¹⁹ have confirmed it microscopically. Volkert²⁰ observed in rabbits that the injection of india ink caused the disappearance of 20 per cent of the antithrombin, being the fraction in the blood considered by him to be heparin. Also it prevented the rise in this fraction which he normally observed after the injection of protein. The effect of india ink, he concluded, was due to an effect on the red cells whereby they could bind heparin.

TABLE 4—Effect of India Ink Injections on the Heparin Tests

Exp	Dog	Time after india ink injection	In vitro test		In vivo test Peak clotting time	Duration
			Clotting Time	Slope		
			min		min	min
35	E	preinjection	3 0	1 64	>60	36
		10'	5 4	0 37	—	—
		3 hours 40'	—	—	10	43
		6 days	3 7	0 96	14	29
56	E	preinjection	2 0	2 30	42	39
		4 hrs	3 7	1 24	12	23
37	F	preinjection	2 1	0 85	16	30
		4 hrs	2 8	0 96	4	20

A series of dogs was standardized, and 5 cc of a 5 per cent suspension of india ink (Higgins) was given intravenously. The response of the animals to heparin was then again determined. The tests were conducted at various times after the india ink. Immediately after the injection the blood was hypercoagulable to such an extent that it was not possible to conduct the tests. In only one case (experiment 35) was it possible to obtain a satisfactory heparin curve immediately after the injection. The india ink had disappeared from the plasma ten minutes after the injection as judged by the color of the plasma. The most interesting and consistent effect of india ink was observed three to four hours after the injection. Examples of this are shown in table 4. At this time, a marked flattening of the response to heparin *in vivo* was observed as shown by the marked decrease in the peak clotting time. The *in vitro* test showed some decrease in the sensitivity to heparin. However, this did not always appear to be responsible for the marked effect on the *in vivo* curve. The duration of the *in vivo* test was decreased in some cases but not consistently with the decrease in peak clotting time. The normal clotting time of the animal was lengthened. The effect lasted partially as long as six days after the injection of the ink.

The results resemble those of Volkert, suggesting an interference in the reaction of heparin with the clotting system rather than either a change in the coagulability (which would be demonstrated by the *in vitro* test) or a change in the ability of the body to inactivate heparin (which would be demonstrated by the duration of the hypocoagulability *in vivo*). Rather, there is an increase in the blood of nonspecific factors which interfere with heparin action. Since blockade of the reticulo-endothelial system with india ink does not increase the duration of hypocoagulability after heparin injections, the reticulo-endothelial system is probably not involved in the disappearance of heparin from the circulation.

FIG. 4 Effect of nephrectomy and evisceration on the response to heparin. Left-hand figure, *in vitro*, right-hand figure, *in vivo*. x—x animal under pentobarbital anesthesia before operation, ●—● same animal after removal of the kidneys + --- + animal under pentobarbital anesthesia, ○ --- ○ same animal after evisceration.

Effect of nephrectomy and evisceration on heparin sensitivity. As shown in figure 2, the anticoagulant action of heparin disappears rapidly from the circulation. Howell suggested that heparin was excreted by the kidneys, and evidence in favour of this view has been obtained by Wilander²¹ and Copley and Schnedorf²². However, Jaques¹ and Reinert and Winterstein²³ did not detect any excretion in the dog or in man. As a more direct test of this problem, both kidneys were removed from four dogs under pentobarbital anesthesia. These animals had been carefully standardized on heparin and the heparin sensitivity was again tested immediately after the operation while the animals were still under the anesthetic. The results of one experiment are shown in figure 4. It can be seen that there is no change in the response

to heparin either *in vitro* or *in vivo*. While the points of the *in vitro* curve do not lie on the straight line as closely as is usually the case, there is no significant difference between the values before and after operation. One animal showed an increase in clotting time and one showed a decrease, after the operation. In these experiments, the curves after operation were simply displaced by a corresponding amount, indicating that there had been no change in sensitivity to heparin *in vitro* or *in vivo*.

Since the kidneys do not appear to be directly responsible for the rapid disappearance of hypocoagulability after heparin injections, the gastrointestinal tract was similarly investigated. Three dogs were carefully standardized for the heparin test under pentobarbital anesthetic. The gastrointestinal tract and related organs, including the spleen, were then removed. Since removal of the liver is followed by a rapid fall in prothrombin, introducing a further difficulty in interpreting the test, care was taken not to damage the liver or hepatic artery. After completion of the operation, a good pulse was observed in the hepatic artery. The response of the animal to heparin was determined one hour and three hours after the operation. Glucose was given postoperatively to two animals, but not to the third. No difference was observed in the response of the three animals.

The results obtained in one animal are shown in figure 4. After the operation the animal's blood was hypercoagulable, as shown by the lack of response to heparin added *in vitro*. The response *in vivo* was also changed. A much greater peak clotting time was obtained. This was to be expected, since in removing the viscera we also removed a large proportion of the effective blood volume, so that the heparin concentration of the 30 unit/Kg dose was proportionately much greater when calculated as units/cc of blood. However, the clotting time returned to normal in 35 minutes, compared with 30 minutes before operation. It is evident that the gastrointestinal tract likewise is not responsible for the disappearance of heparin from the circulation.

SUMMARY

1. The relationship between clotting time and heparin dosage has been studied in the dog.

2. On the addition of heparin to blood *in vitro*, a linear relation is found between heparin dosage and the logarithm of the clotting time obtained. The sensitivity of the blood sample to the action of added heparin is influenced both by the individual (coagulability of the blood before withdrawal) and by the technics of withdrawal and of determination of the clotting time. It is indicated that alterations in the latter may be used to extend the range of measurable hypocoagulability due to heparin. Incubation of heparin with blood for ten minutes increases its anticoagulant effect.

3. When moderate doses of heparin are injected intravenously, five to fifteen minutes are required for the clotting time to reach a maximum. No evidence of a biphasic response was obtained. The maximum clotting time obtained is greater than it is with the same amount of heparin added to the blood *in vitro*, due to the effect of incubation of heparin with blood on its anticoagulant activity. The in-

terval required for the clotting time to return to normal is quite short, and with a given dosage is constant with different animals. Factors influencing the relation between duration of hypocoagulability and dosage are discussed.

4. A test has been devised to determine the sensitivity of the animal to the anticoagulant action of heparin. The clotting time response to certain concentrations of heparin added to the blood *in vitro* is determined. A fixed dose of heparin is then injected intravenously and the clotting time response is again determined. The response *in vitro* measures the sensitivity of the clotting system to heparin, while the *in vivo* response, when interpreted in the light of the *in vitro* response, measures the ability of the body to remove heparin from the circulation.

5. By means of this test, it has been determined that anesthesia with pentobarbital decreased the coagulability of the blood, urethane had no effect on coagulability, while the effect of ether was variable. The injection of india ink and evisceration caused a hypercoagulability, while removal of the kidneys had little effect.

6. When the sensitivity of the blood to the anticoagulant action of heparin was tested during these procedures, pentobarbital and nephrectomy had no effect, ether caused an increase in sensitivity, urethane a decrease. The injection of india ink and also evisceration markedly decreased the sensitivity of the blood to the anticoagulant action of heparin.

7. Anesthesia with pentobarbital, ether or urethane, the injection of india ink, removal of the kidneys, or removal of the gastrointestinal tract, had no effect on the duration of heparin action in the body.

ACKNOWLEDGMENT

We are greatly indebted to Professor C. H. Best for his interest and encouragement in these studies, and to Dr. J. Markowitz for performing the experimental surgery for us. The study was supported by a grant from the John and Mary R. Markle Foundation.

RESPONSE OF TROPICAL SPRUE TO VITAMIN B₁₂

By TOM D SPIES, M D , AND RAMON M SUAREZ, M D

THROUGHOUT the world the macrocytic anemias are of great interest to physicians Sprue, perhaps the most common syndrome in this group, has a geographic distribution restricted to India, Ceylon, the Malay States, the Philippine Islands and, to a lesser extent, the Southern United States and the countries bordering or near the Caribbean sea After Minot and Murphy¹ demonstrated that liver was effective in promoting blood regeneration in persons with Addisonian pernicious anemia, it was found that tropical sprue could be treated with liver and liver extracts with some success In recent years two pure chemical compounds, pteroylglutamic acid (folic acid) and 5-methyl uracil (thymine), have been shown to be effective in the treatment of sprue²⁻³ Still a third chemical substance, vitamin B₁₂, has recently been isolated which is infinitely more potent per unit of weight than liver extract, folic acid, or thymine, but it has not been synthesized, and at the present time it is available only in small amounts for experimental use This compound, shown by Shorb⁴ to be a growth factor for *Lactobacillus lactis* Dorner and to bear an almost linear relationship to the potency of concentrated liver extract, was isolated from liver by Rickes, Brink, Koniuszy, and Folkers⁵ West⁶ has demonstrated its positive hemopoietic action in three cases of pernicious anemia Spies, Stone, and Aramburu⁷ have reported both a hematologic and a clinical response in two cases of pernicious anemia, two cases of nutritional macrocytic anemia, and one case of nontropical sprue Spies, Garcia Lopez, Milanes, Lopez Toca, and Culver⁸ have reported a hematologic and clinical response following its administration to two cases of tropical sprue The present communication is concerned with the response of five cases of tropical sprue in Puerto Rico to vitamin B₁₂

These patients were selected for study using the following criteria (1) The patient must have macrocytic anemia as determined by Wintrobe indices (2) The bone marrow must show the typical megaloblastic type of maturation arrest seen in macrocytic deficiency anemias (3) the erythrocyte counts must be below 2.5 million (4) The patient must be untreated, or must not have been treated recently enough to interfere in any way with the evaluation of the vitamin B₁₂ (5) He must have persistently low reticulocyte counts during the preliminary period of

From the Northwestern University Department of Nutrition and Metabolism and the School of Tropical Medicine of Puerto Rico

This study was aided by a grant from the Martha Leland Sherwin Memorial Fund

The vitamin B₁₂ was furnished by Dr. Augustus Gibson, Merck & Company, Inc.

FIG. 2. HEMOPOIETIC RESPONSE OF PATIENT (D R) WITH TROPICAL SPURIE TO VITAMIN B₁₂.

FIG 3 HEMOPOIETIC RESPONSE OF PATIENT (A S) WITH TROPICAL SPRUE TO VITAMIN B₁₂

FIG 4 HEMOPOIETIC RESPONSE OF PATIENT (M C) WITH TROPICAL SPURIE TO VITAMIN B₁₂

FIG 5 HEMOPOIETIC RESPONSE OF PATIENT (J G) WITH TROPICAL SPRUE TO VITAMIN B₁₂

observation (6) He must have alimentary tract symptoms consistent with diagnosis of tropical sprue

Hematocrit studies were made using pipets certified by the United States Bureau of Standards The hemoglobin content was determined by means of the Photovolt photoelectric hemoglobinometer, calibrated so that 14.5 grams was equivalent to 100 per cent The reticulocytes were counted in dry preparations of brilliant cresyl blue counterstained with Wright's stain Platelets were enumerated in the counting chamber used for red blood cells by means of a fresh solution of sodium citrate

Sternal bone marrow was obtained by aspiration prior to treatment and again near the peak of reticulocytosis

Gastric analyses were performed in each case

On admission the patients were given the 'preliminary' sprue diet previously described⁹ and were maintained on this diet throughout the period of study After the baseline studies were completed, the five patients selected were treated and the results are shown in figures 1, 2, 3, 4, and 5, which illustrate the hematologic response in each case

OBSERVATIONS

Reticulocytosis occurred in each case and usually began around the fourth day, being followed by erythrocytosis and hemoglobin production Coincidental with the reticulocytosis, clinical improvement occurred in cases 1, 2, 3, and 5 This improvement was characterized in each patient by a gain of strength and a great increase in appetite and feeling of well-being As can be seen by a glance at the figures, the red blood cells and the amount of hemoglobin increased after the peak of the reticulocytosis, but in no instance did these patients respond maximally

In case 4, receiving 4 micrograms of vitamin B₁₂, it is questionable whether the response which occurred was due to the very small amount of vitamin B₁₂ administered This case responded in a characteristic way to large amounts of pteroyldiglutamic acid (fig. 4)

Case 3, who responded both clinically and hematologically to a single dose of 20 micrograms of vitamin B₁₂, ate 400 grams of liver fifteen days later A spectacular improvement occurred (fig. 3), this figure also shows the subsequent response to the administration of pteroyltriglutamic acid

It is of considerable interest that after a second injection of vitamin B₁₂ in case 5, she again responded well A similar response was noted following additional injections of vitamin B₁₂ in cases 1 and 2 Not only was there an additional increase in blood values, but additional clinical improvement occurred and the alimentary tract function tended to return toward normal as the bowel movements decreased in number and the stools became darker and better formed

SUMMARY AND CONCLUSIONS

These findings show that the administration of vitamin B₁₂ to patients with tropical sprue was followed by general clinical and hematologic improvement provided the dosage was adequate A single dose of 4 micrograms administered in case 4

produced little or no change. The larger dosage of 10–25 micrograms administered in the other cases was accompanied by striking increase in strength and vigor and a decrease in the diarrhea, however, in no instance was a maximal dose given and these patients quickly tended to relapse clinically and hematologically. They could be relieved promptly again either by another injection of vitamin B₁₂ or by a compound of folic acid (The conjugated compounds of folic acid used in these cases were used for experimental purposes, and they produced the same hematologic response as that of folic acid per se.) Case 3, who had an excellent hematologic response after eating one serving of 400 grams of liver, is regarded as especially significant in that it suggests that, as powerful as vitamin B₁₂ is as a therapeutic agent, it is more effective when given with liver. It is especially noteworthy that cases 1 and 2, who had three injections of vitamin B₁₂, have had steady clinical and hematologic improvement. The reader should have in mind that a single injection of approximately 100 micrograms of vitamin B₁₂ probably would be needed to produce a full hematologic response in persons so ill. This tentative appraisal would suggest that this therapeutic compound, per unit of weight, is more effective in treating human disease than any compound that yet has been used.

ACKNOWLEDGMENT

We are very much indebted to others who have aided us in selecting cases and in observing results. Especially we wish to thank Dr. F. Hernandez-Morales, Dr. Hector Marchand, Miss Clemencia Benitez Gautier, and Miss Sara Torres.

ADULT GAUCHER'S DISEASE, WITH SPECIAL REFERENCE TO THE VARIATIONS IN ITS CLINICAL COURSE AND THE VALUE OF STERNAL PUNCTURE AS AN AID TO ITS DIAGNOSIS

By J. GROEN, M D , AND A. H. GARRER, M D

GAUCHER'S disease is a rare, often familial disease, distinguished by the presence of characteristic cells in the organs of the reticulo-endothelial system (spleen, liver, lymph glands, bone marrow). The protoplasm of these cells has a typical cytologic appearance due to the presence of a special lipoid, the so-called Gaucher substance or kersin.

The increase in our knowledge of the underlying pathologic process has gradually facilitated the possibility of a clinical diagnosis during life. Gaucher⁶ described the disease in 1882 as an "idiopathic hypertrophy of the spleen, without leukemia," but he mentioned in his paper that in the course of the disease the liver also became enlarged. Another sign, the swelling of lymph glands, has proved of little diagnostic value as the swollen glands are usually situated inside the body. An important observation, of help in diagnosis, may be a peculiar yellow pigmentation which develops in some of the cases on the face and in the conjunctivae in the form of wedge-shaped pingueculae. Bloem, Groen and Postma² and Kveim^{11, 12} drew attention to the presence of a characteristic pigmentation that occurred fairly commonly on the lower legs in their patients suffering Gaucher's disease. If present, this pigmentation is almost pathognomonic of this condition. Bloem, Groen and Postma² described a few other minor signs that might be of additional help in the diagnosis, viz., the presence of a peculiar malar flush and the occurrence of myopia.

Examination of the blood may yield further useful information: a hypochromic anemia with leukopenia and thrombopenia are usually present, the cholesterol content of the blood is normal or very often, low. However, this hematologic syndrome occurs also in other conditions associated with splenomegaly so that its diagnostic importance is not decisive. The majority of patients exhibit some degree of hemorrhagic diathesis.

X-ray examination has supplied us with another means of supporting a clinical diagnosis of Gaucher's disease. Some of the early investigators, most notably Brill, Mandlebaum and Libman,³ demonstrated that Gaucher cells accumulate in various parts of the bones where they ultimately produce macroscopic areas of bone destruction. Further experience has shown that these bone lesions, although they may occur almost anywhere, show a predilection for certain areas. The head and neck of the femur are often affected, which gives rise to a typical x-ray picture. The lower ends of the femora often contain so many Gaucher cells that they become swollen and present a shape similar to an Erlenmeyer flask.

Even in the presence of these clinical signs, however, a diagnosis of Gaucher's

From the Department of Medicine, University of Amsterdam, Wilhelmina Gasthuis.
Publication of this report was delayed by the war and the occupation of The Netherlands.

disease could very often not be made with absolute certainty. The introduction of the sternal puncture was therefore a great advance. It is the purpose of this paper to present some cases of Gaucher's disease with special reference to the importance of sternal puncture as an aid to the diagnosis. At the same time this will give us an opportunity to describe the clinical features which these cases presented. Some of the cases have been described by others,^{4 13 14, 15 26} and by one of us,² years ago and it seems appropriate to present their development since that time.

CASE REPORTS

CASE I

Mrs E R B, born in 1890, a Jewish married woman, was first seen in the out-patient department on January 5, 1938.

History The patient had always been a weak girl. When she was 13 years old she noticed a lump in the left side of the abdomen which grew slowly during the years that followed. A tendency to bleed manifested itself at an early age, later on bleeding was especially troublesome after tooth extractions and during menstruation. In 1922, when she was 32 years old, a splenectomy was performed by Dr Pimentel. On microscopic examination this spleen was found to contain the typical Gaucher cells.*

After the operation her condition remained fairly satisfactory until 3 years before admission, when she began to suffer from palpitation, dyspnea on exertion, and a persistent cough. Occasionally she would bring up some sputum, sometimes blood-stained. The urine had become scarce and darker than it had formerly been. She was thirsty but had not noticed any swelling of the feet.

The family history did not reveal other cases of a similar nature. The patient's father died of cancer of the rectum, her mother of apoplexy. Both died in a hospital, no enlargement of the spleen or liver had been found in these individuals. The patient's husband, two sisters, one brother and her two children, 25 and 19 years old respectively, were also examined by us. None of them showed any of the clinical signs of Gaucher's disease.

Physical examination The patient appeared weak and in a rather poor nutritional state. There was marked cyanosis of nails, ears, lips and cheeks. The entire skin had a somewhat yellowish tinge. Both conjunctivae showed typical pingueculae. There was bilateral myopia.

The heart was markedly enlarged toward the left, the apex-beat was visible in the anterior axillary line. The right border extended 1 cm. outside the right sternal line. All heart sounds were loud, the first mitral and the second pulmonary sounds were especially accentuated. There was normal percussion over both chest fields anteriorly, but posteriorly there was dullness on the right side, reaching from the spine of the 7th thoracic vertebra downward. On auscultation, fine crepitant rales could be heard over both lungs, over the right lower lobe the breath sounds were diminished. The abdomen showed a large surgical scar. The liver was enlarged and firm and reached downward to the umbilicus.

The right lower leg showed pigmentation of the skin due to the application of heat. The typical Gaucher pigmentation was not present. The blood pressure was normal.

The urine contained some albumin ($\frac{1}{4}$ per cent), an excess of urobilin and some casts. Morphologic blood studies showed hemoglobin, 110 per cent, erythrocytes, 5,530,000, and leukocytes, 11,200. The cholesterol, lipid phosphorus, and lipid nitrogen content of the blood plasma were normal.

The x-ray picture showed a diffuse decalcification of the bones but no localized areas of destruction. The heart appeared displaced and/or dilated to the left. There was fluid in the right hemithorax. The pulmonary artery was abnormally prominent.

Sternal puncture revealed many typical Gaucher cells.

The clinical diagnosis was Gaucher's disease with a tentative diagnosis of mitral stenosis or cor pulmonale due to increased resistance of blood flow in the smaller circulation. It was supposed that the obstruction in the smaller circulation was due to an accumulation of Gaucher cells in the lungs. It was

* The specimen was demonstrated by M. Elshout in a meeting of the Netherlands Pathological Society.⁴

significant that in this case (where the spleen had been removed) leukocytosis was present instead of the usual leukopenia. The thrombopenia, however, persisted after splenectomy.

The condition gradually became worse. On August 10, 1938, the patient was admitted to the hospital. This time there was fluid on both sides of the chest. During her stay in the hospital the patient had repeated attacks of severe dyspnea with extreme cyanosis. She died suddenly during one of these attacks. Her age at death was 48 years.

Permission for postmortem examination could not be obtained, but punctures of the liver and the sternum were performed immediately after death. In both, Gaucher cells were found. The number of these cells in the bone marrow appeared to be far greater than in the liver.

CASE 2

Mr. Fa, a Jewish lawyer, born in 1901, of German origin, was first seen on October 27, 1937.

History. The patient had no complaints at all until 1932, when he began to suffer from pain in the right leg, which started in the buttock and radiated toward the foot. The pain disappeared after a period of rest in bed. In 1933, he had similar pains in both legs, which disappeared spontaneously after ten days. In May, 1934, the same pain, which he considered to be sciatica, recurred in the left leg, this time it stayed there. All movements in the left hip joint became increasingly difficult, it was impossible for him to cross his legs when sitting. Now and then he felt distinct crepitation in the left hip joint on movement.

In October, 1934, he also experienced pain in the right side of his back. The local doctor suspected gall stones and sent him to a roentgenologist. The night before the x-ray examination, the patient took tetraiodo-phenolphthaleine and the following morning he went to the hospital without breakfast. He cannot remember what happened to him that morning, but apparently he arrived at the hospital in a dreamlike state. The x-ray picture was made, but the patient's memory returned only when, after coming home at 11:00, he took his breakfast. He then told his family that he had to go to the hospital for the x-ray picture, he had no idea that he had already been there. No gall stones were found on this occasion. Subsequently he has had similar states of mental confusion. Finally, they occurred almost every morning between awakening and breakfast. After breakfast the symptoms disappeared. A sister of the patient noticed that during these trances his pupils became enlarged and that the patient perspired and trembled all over. At this time the patient was examined in Düsseldorf where the diagnosis of cerebral tumor was made. Lumbar puncture showed a normal result. Afterwards an enlarged spleen was found and a diagnosis of leukemia was put forward. The patient thereupon went to Frankfurt where a low blood sugar was found during the attacks. The spells disappeared after administration of glucose, they could be induced by injection of insulin. Consequently, a diagnosis of islet cell tumor of the pancreas was established. In the same hospital an arthritis deformans of the hip joint with destruction of the head of the femur was also found for which an orthopedic support was prescribed.

As the condition became worse, the patient was operated on and a tumor the size of a nut was removed from the pancreas. On microscopic examination this appeared to be an islet-cell tumor. After this operation the attacks of hypoglycemia disappeared. An explanation for the enlarged spleen was not found, the condition of the left leg remained unchanged.*

Family history revealed that the patient's father died of arteriosclerosis, his mother of kidney trouble. One sister has gall stones. She showed no clinical signs of Gaucher's disease on examination by one of us. One brother is suffering from Gaucher's disease. The diagnosis was established on clinical grounds and verified by sternal puncture elsewhere. A second brother is reported as suffering from a slightly enlarged spleen and a moderate secondary anemia. A third brother died when he was five months old. A cousin on the maternal side also suffered from Gaucher's disease, the diagnosis was said to have been established by pathological examination of an extirpated spleen.

Physical examination. The patient appeared in a moderately good state of health. The skin of the face was yellow, but there was no jaundice. Small pingueculae were present in both eyes. Skin and mucous membranes were somewhat anemic. Around both ears the skin showed some vitiligo. The skin of the entire body was somewhat pigmented, probably partly due to exposure to the sun. Examination of the eyes revealed a bilateral myopia of 2.5 diopters. Otherwise, neck, heart and lungs were all normal. The abdomen was diffusely swollen. The liver was palpable, two fingers below the costal margin, with

* The case up until this stage has been described by Reiter.*

rounded edge and smooth surface. The spleen was markedly enlarged, the organ reached downward to the level of the umbilicus and had a rounded edge. Both organs were firm in consistency and not tender.

The left leg was considerably shorter than the right, it was supported by an orthopedic apparatus. All movements in the left hip joint were restricted, especially adduction and rotation. Movement in the right hip was completely free. There was no tenderness on pressure. There was no abnormal pigmentation of the legs. Reflexes were completely normal.

FIG. 1, CASE 2. LOCALIZED AREAS OF RAREFICATION IN BOTH FEMORA.

The urine contained some urobilin but no further abnormalities. The sedimentation rate was normal. The blood picture showed hemoglobin, 85 per cent, erythrocytes, 5,300,000, leukocytes, 4,700, blood platelets decreased. The lipid spectrum showed free cholesterol 44.5 mg per cent, cholesterol esters 99.1 mg per cent, total cholesterol 143.6 mg per cent, lipid nitrogen 24.7 mg per cent, lipid phosphorus 6.29 mg per cent, total lipid and fat (without cholesterol) 269.4 mg per cent.

On roentgenological examination the head of the left femur appeared flattened and partly destroyed.

In the head and in the shaft of both femora several areas of rarefaction were present (fig 1) The lower ends of both femora were swollen, (fig 2) the left tibia showed several areas of decalcification (fig 3)

Microscopic examination of the sternal marrow showed the typical Gaucher's cells

FIG 2, CASE 2 LOCALIZED DECALCIFICATION IN BOTH TIBIAE

The patient was put on a vegetarian diet. Except for occasional periods of sciatica he had been relatively free from symptoms when in 1940 he suffered a spontaneous fracture of the shaft of the right femur which brought him to the hospital again. It was then found that the bone lesions had increased.

in many areas. The fracture was treated by surgical extension and healed with satisfactory callus formation (fig. 4). However a bone abscess formed on the spot where the nail had been driven through

FIG. 3, CASE 2. LOCALIZED DECALCIFICATION IN BOTH TIBIAE

the head of the tibia. The pus contained some large pale cells that might have been Gaucher cells. The abscess healed after drainage and the patient's condition since has been stationary. Later he gave up the diet and this did not seem to make any difference in the slow course of his condition.

FIG 4, CASE 2

Spontaneous fracture healing with callus formation of the right femur. Localized decalcification and swelling of lower end of the femur (Erlenmeyer flask appearance)

CASE 3

Mr Fl, a 30 year old Jewish business man of German birth presented himself for the first time on March 25 1938

History For one year he had had increasing difficulty in walking because of pain in the left knee and left buttock, which had become almost unbearable in the last few months. The patient did not present these complaints in connection with another disease from which he had been known to have suffered

for at least twenty years. Since that time he had seen several doctors, because of frequent hemorrhages from the nose, diarrhea and occasional fever. He had been told that he had a large liver and spleen. There were no known cases of a similar disease in his family. His mother was examined and found to be normal. His father had died from a heart attack. The patient was an only child. He was married to a normal wife. He had one child, a boy, five years old, who was found to be normal.

When the patient was 10 years old he was operated on for appendicitis. In 1916, he suffered from pericarditis. Tonsils and adenoids had been removed in 1926, the operation was followed by severe hemorrhage.

Physical examination The patient appeared to be in moderately good health. He had a myopia of both eyes (D.4). There were no pingueculae, the pupils were normal. There was no abnormal pigmentation of the face. Mouth, throat and neck were normal. The abdomen was greatly distended. The spleen protruded from under the costal margin and reached almost the inguinal ligament. The liver was also enlarged and firm and almost reached the umbilicus.

Reflexes were normal. The left leg was about 2 cm. shorter than the right. Movement in the left hip joint was extremely painful and greatly restricted. There was pain on pressure in the hip and in the groin. There was no abnormal pigmentation on the legs.

The urine contained some urobilin, but was otherwise normal. The stools contained no occult blood. The sedimentation rate was 12 mm. after one hour (Westergren). The blood picture showed hemoglobin, 64 per cent, erythrocytes, 3,400,000, and leukocytes 3,000. Only a few thrombocytes were present in the smear. Calcium, inorganic phosphate and phosphatase and nonprotein nitrogen values in the blood were normal. The lipid spectrum was essentially normal: free cholesterol, 55.6 mg. per cent, cholesterol esters, 66.6 mg. per cent, total cholesterol, 122.2 mg. per cent, lipid phosphorus 6.51, lipid nitrogen 27.82 mg. per cent, total lipid fats (without cholesterol) 276 mg. per cent. The patient was put on a low calcium diet for balance studies. No abnormalities in the excretion of calcium or phosphate in the feces were found, but the excretion of calcium in the urine was low, 44, 58 and 94 mg. per 24 hours, respectively, on three consecutive days.

X-ray examination showed destruction of the head of the left femur. Sternal puncture revealed the presence of many Gaucher cells.

Course The left leg was immobilized in a plaster cast. After six months the local condition seemed improved. The pain disappeared, and except for occasional attacks of sciatica the patient managed to go about his business. From 1939 onward he began to suffer from attacks of severe pain in the left side of the chest and abdomen, which were followed each time by periods of fever. On one occasion a splenic friction rub was heard. It was felt that these attacks were due to splenic infarcts with perisplenitis. The attacks recurred so often that the patient was practically confined to bed. In view of this situation, splenectomy was performed in June of 1941. The operation was extremely difficult due to extensive adhesions between the spleen and the diaphragm. Profuse bleeding occurred, and the patient succumbed 12 hours postoperatively, in spite of repeated transfusions. Permission for postmortem examination could not be obtained. The spleen showed the typical picture of Gaucher's disease. Unfortunately, the chemical investigation was interrupted when the chemist was deported to a German concentration camp from which he did not return. The dried spleen was lost on this occasion.

CASE 4

W. de B., born in 1909, a male office clerk, aged 25, the only patient in this series who was not Jewish, was first seen by one of us in February 1934, when he was admitted to the Binnengasthuis because of abdominal discomfort.

History Apart from scarlet fever, diphtheria, and measles, he had never been ill. For several years he had noticed an increasing tendency to bleed. His sister, the only living member of the family, was normal. There was no history of any other member of the family having had a similar disease.

Physical examination There was a slight malar flush and bilateral pingueculae. Both eyes were myopic. The chest was normal. Both the liver and spleen were enlarged, the latter reaching the anterior superior iliac spine. His legs showed a peculiar patchy brown pigmentation which ended sharply at the instep of each foot. The urine was normal. For laboratory examination (leukopenia and thrombocytopenia) the reader is referred to the first publication.*

* This case was reported (Case 5) by Bloem, Groen and Postma.²

Since 1934 his condition remained fairly satisfactory on a vegetarian diet, but on June 28, 1938, he was admitted to the department of medicine of this hospital because of sudden severe pain in the sacral region after slight trauma

On physical examination, it appeared that the liver and spleen had increased in size. These organs were in close contact in the left mamillary line, where they could be felt to rub against each other. A typical friction rub could be heard over the spleen. The pigmentation of the legs had also increased in area and intensity.

Liver function tests (galactose and bromsulphalein excretion) were normal. Vandenberg (indirect), 0.96 mg per cent. Sedimentation rate, 61 mm after one hour.

The blood picture showed hemoglobin, 59 per cent, erythrocytes, 3,100,000, and leukocytes 2,100.

Toxic granulation in about 30%, marked anisocytosis, poikilocytosis and polychromasia.

In 1934, a diagnosis of Gaucher's disease had been made on clinical grounds only, this time a sternal puncture was performed. The typical cells were found.

X-ray examination showed no gross abnormality of the bones. The pain in the back disappeared rapidly after rest in bed and physical therapy.

The patient went home without pain but otherwise his condition had remained unchanged. He was a great believer in the favorable influence of a purely vegetarian diet on his condition. His diet consisted of whole wheat bread, oleomargarine, jam, vegetables, potatoes, peas, beans, nuts and fruit. He gradually lost a good deal of weight on this diet. He developed muscular atrophy and his muscular strength diminished markedly. He also developed pitting edema of the feet. The possibility that this might be due to a lack of animal food was pointed out to him but he continued on his exclusive vegetable diet. He died at his home in 1939 in a state of general exhaustion, possibly from protein deficiency.

CASE 5

R. P., a 43 year old Jewish single female school teacher was admitted in 1938 for recurrent attacks of sciatica. These attacks had started five years ago in the right leg, lasting only for about a fortnight. The pain radiated from the buttock along the back of the leg to the lateral side of the lower leg. Later she had similar periods of pain in the left leg. Gradually the pain became more severe, it lasted a longer time and the patient could hardly walk.

Apart from this she had very few complaints. She had noticed that her abdomen was a little swollen but she had attributed this to her getting fat. She had also noted a tendency to bleed, which was especially cumbersome during menstruation.

Physical examination revealed myopia, malar flushes, a somewhat increased second pulmonic sound, enlarged spleen which reached down as far as the umbilicus, a liver which was about 1 or 2 fingerbreadths enlarged, and a diffuse yellowish tinge of the skin of the whole body. There was a typical Lassegue sign bilaterally. Reflexes and sensitivity were normal. Movements such as turning around in bed, were extremely difficult. The blood picture showed leukopenia and thrombopenia, with little or no anemia. Numerous Gaucher's cells were found in the sternal marrow.

Family history did not reveal any known cases of Gaucher's disease. The patient's mother had died of carcinoma of the uterus. The father was examined and found to be normal. She was one of twelve siblings. Two of the siblings who could not be examined had a suspicious history of Gaucher's disease. The disease however was found with certainty in a younger brother (case 6).

Course The patient's condition fluctuated. When one day she developed a typical biliary colic with jaundice. She was operated upon and a gallbladder full of stones was removed. She made a satisfactory recovery but her sciatica kept on troubling her from time to time. In 1943 she was arrested by the Germans and transferred to a concentration camp from which she returned with a pulmonary tuberculosis.

CASE 6

M P, a brother of Case 5, a 42-year old married Jewish business man, had no complaints. One year ago he had had an attack of sciatica which lasted for only ten days.

On physical examination, the spleen was found to be two fingerbreadths below the costal margin and the liver was one fingerbreadth enlarged. He had myopia and malar flushes exactly similar to those of his sister. These flushes were not presented in the nonaffected members of the family. Sternal puncture revealed Gaucher cells. His wife was examined and found to be normal. Two children, 6 and 3 years old, respectively, were apparently normal.

The patient's condition was followed. He had no complaints when he was seized by the Germans and deported to Poland. He did not return.

CASE 7

A X, a Jewish girl, born September 15, 1923, was seen for the first time in January, 1939, through the courtesy of Professor Van Creveld.*

History When she was two years old, a swelling of the abdomen was noticed. Professor de Lange, who was the first to make the diagnosis in 1929, found an enlarged spleen and liver, hypochromic anemia, leukopenia and thrombopenia, with marked hemorrhagic diathesis. There were no changes in the bones at that time. Gradually the typical Gaucher pigmentation developed on both legs.

The diagnosis of Gaucher's disease could be made with certainty because in a sister (E X, Case 8) splenectomy had been performed and Gaucher cells had been found in the spleen.

Since the report in 1931 by de Lange,¹³ the patient's illness progressed steadily¹⁴ so that when we saw her the liver and spleen had become excessively enlarged. There were also radiologic signs of involvement of the bones. In the sternal marrow many typical Gaucher cells were found.

Course The condition had become gradually worse when the patient and her parents were deported in 1942 to a German concentration camp from which they never returned.

CASE 8

E X, a Jewish girl, born March 19, 1927. She is a sister of the patient reported above (Case 7). She was also described in de Lange's papers. She was first seen in April, 1939, through the courtesy of Professor van Creveld.

History This child showed an enlargement of the spleen at an early age. Splenectomy was performed in 1930 and Gaucher cells were identified in the spleen. A detailed chemical examination of the spleen was carried out by Westenbrink³⁵ who isolated and identified kersin.

In 1938, she began to complain of pain in the left leg, and fever. Extensive cystlike rarefactions were present in the x-ray pictures of the left femur. Similar attacks of pain recurred regularly.

Physical examination The patient showed slight generalized swelling of the lymph glands and a very large liver of firm consistency, reaching down to the umbilicus. Both lower legs showed the typical leaden brownish-grey pigmentation. Liver function tests were normal. It is curious to note that in this case (as in Case 1 where splenectomy had also been performed) the typical leukopenia was replaced by a slightly high leukocyte count. The blood picture was as follows: hemoglobin, 80 per cent, erythrocytes, 4,570,000, leukocytes, 10,400, platelets 120,000.

The blood chemistry findings were essentially normal. Sternal puncture revealed the presence of many typical Gaucher cells.

Course This girl shared the fate of her sister.

* Cases 7 and 8 have been described by de Lange¹³⁻¹⁵ and Heilbron.⁷

CASE 9

The occurrence of Gaucher's disease in two sisters (Cases 7 and 8) naturally focused our attention to the possible presence of the disease in one of the parents. Both had been examined in 1931 by de Lange and on that occasion had not shown any physical abnormality.

On re-examination, the father (P X) had no complaints at all. In addition to a chronic bronchitis, we found pingueculae on both eyes and a few scattered grey spots on the skin of the legs.

The mother (E X-C) gave a history of prolonged bleeding after slight injury and during menstruation. No abnormalities were found on physical examination.

Hematologic examination in both cases yielded normal results.

Sternal puncture was carried out in both parents. No typical Gaucher cells were found but the father's marrow contained a rather high percentage of unclassified cells of the type most authors would call reticulum cells or stem cells. Some of these resembled in appearance Gaucher cells but they were smaller in size. The nuclei of these cells were rather small and in some cells they were shifted to the periphery. The protoplasm stained faintly and was inhomogenous in character. It contained a few irregular vacuoles. Occasionally the cytoplasm resembled in its structure compressed tissue paper. Because of the presence of these cells it was felt that the father of cases 7 and 8, who did not show the clinical characteristics of Gaucher's disease, actually suffered from that disease in a minor degree. Apparently it was he who had transmitted the disease to two of his children where what had been a latent abnormality in his case had given rise to a severe clinical picture at an early age in theirs.

The family tree of Cases 7, 8 and 9 could not be completed. The two girls had three brothers. All were examined clinically and by sternal puncture. In no way was any evidence of Gaucher's disease obtained in them. Other members of the family on either the father's or the mother's side could not be examined. So far as could be ascertained by questioning, there was no case with the clinical features of Gaucher's disease among them.

CLINICAL SYMPTOMATOLOGY

The cases here presented, together with those earlier described by one of us² illustrate most of the salient features of the disease. Many clinicians who have not had a wide experience with this rare malady think of Gaucher's disease as a more or less fixed clinical picture. The reverse is true. There is a remarkable variability in many respects. The disease may make its onset early in infancy, in childhood or early or late in adult life. Its progress may be slow or rapid but it is important to know that its course is always progressive. 'Spontaneous remissions' occur during times when the patient may be relatively or entirely symptom-free but the objective findings have never been observed to regress. As a matter of fact it is the rule that patients do not develop any complaints at all until relatively late, when the spleen and liver have already increased to a considerable size. During the 'silent' or 'subclinical' stage the subject is unaware of his condition until a medical examination happens to take place. In some instances of the present series the disease was discovered only when the relatives of a known case were examined.

Although the disease process seems to be going on continually, the rate of progression varies considerably from patient to patient. The earlier the onset, the more rapid seems to be its course. Cases observed early in infancy almost invariably die within the first year¹⁵, persons with Gaucher's disease in childhood seldom grow older than 50 years, when the disease becomes manifest late in life it does not seem to shorten the lifespan of the individual.

The localization may also show considerable variation. Although spleen and liver are the most prominently involved it is probably safe to say that Gaucher's disease hardly ever spares the bone marrow. However, the presence of the Gaucher

cells does not necessarily upset the *macroscopic* structure of the bone, and thereby the disease may escape detection by radiologic examination, even when bone-marrow puncture or postmortem examination⁷ proves that the cells are there. In the later stages, when massive aggregations of the cells occur, the bones usually show generalized or local osteoporosis.¹⁰ Even in the advanced cases, however, the degree of macroscopic affection of the bone is variable and through this we may encounter considerable variations in the clinical picture. Repeated attacks of low back ache, radiating along the sciatic nerve, either unilaterally or bilaterally, may be the first complaint (cases 5 and 6). Or patients suffering these "osseous forms" may enter the hospital with a spontaneous fracture (case 2) or for what seems a purely orthopedic problem like "arthrosis" of the head of the femur (case 3). Bone abscesses occurred in case 2 and 7.¹⁴

Next to localizations in spleen, liver and bones, foci of Gaucher cells have been found in the lungs,¹⁹ the kidney,⁹ and the brain,²⁹ but these sites are rare.

Complications are frequent in this disease and they also depend on the varied localization. Pigmentation of the legs has been referred to², it occurs relatively late in the disease and has been observed to disappear.¹⁴ Cachexia supervenes in the long standing cases. Case 1 died under a clinical picture of cor pulmonale, possibly due to accumulation of Gaucher cells in the lungs. Other cases we have seen had an increased second pulmonary sound, as a possible indication of pulmonary hypertension. Most remarkable was the combination of Gaucher's disease with an islet cell tumor of the pancreas in case 2. The clinical picture in case 3 was dominated by the successive episodes of splenic infarcts which gave rise to perisplenitis and adhesions around the spleen. Bleeding from these adhesions after splenectomy caused the death of this patient. Case 5 suffered mainly from "symptomatic sciatica". She also had gallstones, a combination we have seen in other cases. She later developed tuberculosis as did Gaucher's original case.⁶ In two cases of this series a splenectomy was carried out successfully. The impression was that the operation does not significantly alter the course of the disease. It certainly did not stop its progress. Interestingly enough, these patients' leukopenia changed into a slight but permanent leukocytosis, whereas the thrombocytopenia and hemorrhagic diathesis remained. Our experience confirms the opinion of several authors³¹ that splenectomy should be carried out only if the spleen itself gives rise to local symptoms which justify its removal. If a patient, as was instanced with case 3, has had repeated attacks of perisplenitis, the surgeon should be prepared to find extensive adhesions between the spleen and the diaphragm. This situation combined with the hemorrhagic tendency caused the death of case 3. Treatment with a purely vegetarian diet appeared to be just as unsatisfactory as splenectomy. Several of our cases have been treated with this diet. The assumption was that by cutting down the exogenous supply of lipoids in the diet, a slowing down in possible storage of the Gaucher substance could be induced. The results have not borne out any support for this hypothesis and it is not unlikely that the restricted diet has hastened the death in case 4.

THE STERNAL MARROW IN GAUCHER'S DISEASE (FIG 7)

In all our cases, the sternal puncture was carried out in the manubrium. Films were made and stained with the May-Grunwald-Giemsa stain. We recommend that several *thin* films be made. The cells should be looked for especially at the end of the smear. The best search for the presence of Gaucher cells is made with a low power lens without oil immersion (fig 5). The typical cells will catch the eye at once by their unusual size, usually 30 or 40 μ , although there may be considerable variation in size. The cells possess one or two nuclei that are usually situated eccentrically. In the smaller Gaucher cells, the nucleus is sometimes in

FIG 5, CASE 3 The aspect of the sternal marrow smear under low power. The Gaucher cells catch the eye by their large size.

the center, in the larger ones it is always displaced toward the periphery. The nuclei are relatively small with a well-stained nuclear membrane. They often contain a nucleolus. The nuclei of the Gaucher cells resemble the nuclei of those cells in the bone marrow which are referred to by some authors as reticulum cells, by others as stem cells, and which are found in a small number in normal bone marrow. As a matter of fact, it is not unusual to find an increased number of these reticulum cells in the marrow smear of patients with Gaucher's disease. Even more commonly one finds cells that are somewhat intermediary in type between the reticulum cell and the Gaucher cell. They have the size of the reticulum cell, or are a little larger, the protoplasm has the faint staining of the reticulum cell but it is more meshy in structure. If they were seen in normal bone marrow one would

call them reticulum cells, in the presence of typical Gaucher cells, one is inclined to regard them as small atypical Gaucher cells. They are probably reticulum cells that have taken up less kersasin and therefore have not changed in type as completely as the typical Gaucher cell. They be might called "early" or "young" Gaucher cells. This view is in accordance with the opinion of most pathologists,

FIG. 6, CASE 3. Gaucher cells under high power illustrating the wrinkled tissue paper appearance of the protoplasm. Note that there is a marked difference in size amongst the Gaucher cells.

who have found similar transitory types between Gaucher cells and reticulum cells in the spleen and therefore regard the Gaucher cells as a transformed reticulum cell (Mandlebaum and Downey¹⁸).

The cytoplasm of the Gaucher cell occupies by far the larger part of the cell body, it stains slightly gray or bluish. In the typical cells it shows a coarse

mesh as if it consisted of compressed tissue paper (fig 6) Sometimes the protoplasm contains vacuoles so that it resembles foam cells Erf⁶ by the use of the supravital staining technic has shown that these vacuoles are artefacts produced during the fixation process The cytoplasm of the Gaucher cell does not stain with any

FIG 7, CASE 3 A drawing of the sternal marrow in Gaucher's disease Three Gaucher cells are drawn separately under high power

of the known dyes, neither does it take the sudan or Goldman's lipid stain or oxydase stains The protoplasm does not show double refraction All these properties fit in with what we know about the characteristics of the lipid kersin that has been isolated from organs containing Gaucher cells

Many authors have reported the finding of Gaucher cells in the bone marrow of living cases Some have used biopsies of the tibia,^{34 1 25 16} but the majority have preferred to use sternal puncture^{28 33 32 5 22 31 21 8 36} Only in a very few cases has the puncture failed to reveal the presence of the typical cells Indeed, one might

very well call the sternal puncture the only method that will enable the clinician to establish a positive diagnosis of Gaucher's disease with certainty. The cells distinguish themselves from all normal bone marrow cells with great ease by their size and structure. The only difficulty that might present itself is in differentiating the cells from the large cells that occur in Niemann-Pick's disease, but the protoplasm in the Gaucher cells is characterized by a fibrillar, meshwork, whereas the Niemann-Pick cells have a foamy appearance.

It is significant that one also finds the Gaucher cells in the marrow in those cases where no gross lesions seem to be present in the bones on x-ray examination. This proves that in most cases the cells are almost universally scattered throughout the bone marrow. It is only in those places where the cells accumulate closely enough to produce atrophy of the bony trabeculae and thinning of the cortex that a "nidus" of some magnitude is formed. It follows that the distinction between visceral types and osseous types of the disease²⁴ has only a relative, and no absolute, meaning. In fact, cases 7 and 8 were described first as purely visceral in type while marked bony lesions developed later. This happened in two sisters, while splenectomy had been performed in only one of them. Splenectomy apparently was useless as a measure against the progression of the disease in the bones.^{34 14}

The importance of sternal puncture as a diagnostic procedure in Gaucher's disease manifested itself especially in the elucidation of the hereditary mechanism in cases 7, 8 and 9. Neither father nor mother of the girls showed clinical evidence of the disease, yet the fact that two of their children were affected could only be interpreted by the assumption that one of the parents was a 'carrier'. By the detection of atypical reticulum cells, resembling Gaucher cells in the father's bone marrow, this assumption was substantiated. This, then, appears to be one of the most important advantages of the sternal puncture, viz., the possibility of establishing an early diagnosis in individuals where the clinical picture is not fully developed. In this connection, the cases of Vogel, Erf and Rosenthal,³⁵ Petit and Schleicher,²³ and Morgans²⁰ are especially interesting. These patients showed no enlargement of spleen and liver (as yet) but only involvement of the bones. Without sternal puncture the diagnosis would have been impossible.

Emile-Weill, Isch-Wall and Perles³³ have advocated splenic and even hepatic punctures as diagnostic procedures. As a matter of fact, hepatic puncture was used by one of us² on a former occasion. However, we feel that the sternal puncture has all the advantages of ease and safety and none of the drawbacks associated with the splenic or hepatic puncture in these patients in whom we know that there is a tendency to bleed.

SUMMARY

The authors present nine cases of Gaucher's disease in which the diagnosis, suspected on clinical grounds, was definitely established by the detection of the Gaucher cells in the smear of the sternal marrow. The authors review the varieties of the clinical picture in this disease. They discuss the importance of sternal puncture with special reference to the possibility of establishing the diagnosis in subclinical cases.

THE HEREDITARY MECHANISM OF GAUCHER'S DISEASE

By J GROEN, M D

THE NUMBER of cases of Gaucher's disease that have been described up to the present time is about 250, but it is probable that many more cases have been observed. Collier's case⁷ was probably the first in which more than one member of the family was found to be affected. After him, Bovaird,⁴ in 1900, described the disease in two sisters. Since then, the familial occurrence of Gaucher's disease has been noted by several observers. About one-third of the published cases have occurred in members of the same family so that a hereditary factor is undoubtedly present. However, the family trees which have been published are quite few, and the exact mechanism by which the disease is inherited is still unknown.

The present author has observed 21 cases of Gaucher's disease. Seventeen were familial and occurred in six different families. Four more cases in these families could not be examined but the available evidence was sufficient to accept them as cases of Gaucher's disease, which brings the total number of familial cases discussed in this report to 25. Four other patients were seen in whom no other members of the family were affected. These were considered to be so-called 'sporadic' cases. The clinical features of our patients have been described elsewhere.^{3, 9} It is the purpose of this paper to review the scanty data on the heredity of Gaucher's disease from the literature and to present the family trees of the cases which have been observed by the author. In reviewing the literature excellent summaries have been found in the papers by Brill, Mandelbaum and Libman,⁵ Hoffmann and Makler,¹¹ Rowland,^{16, 17} Reiss and Kato,¹⁴ De Lange,¹² Atkinson² and Thannhauser.¹⁸ Atkinson's admirable review of the cases of Gaucher's disease described in children appeared in 1938 and has been especially valuable.

In considering the familial cases in the literature, one is impressed by the following facts:

1. There have been 64 familial cases reported which occurred in twenty-five families. The inclusion of the cases described in this report would bring the total up to 89 in thirty-one families.

2. In twenty-three of the families in the literature, the disease occurred in a 'horizontal' spread only. By this is meant that the disease appeared to be present in the members of one generation only, namely in brothers and sisters or in cousins, but not in parents or grandparents or in the offspring of the patients. This peculiarity in the familial incidence of Gaucher's disease is underlined in a statement by Hoffmann and Makler that in no series of children has either of the parents suffered from the disease nor has it been transmitted from any adult to a child.

3. In only two families was there a 'vertical' occurrence described.^{6, 16} In these families the disease was found to be present in two generations, namely, in Rettig's case, in a father and his daughter,¹⁵ and in the case described by Bychowski, in a father and three of his children.⁶ Quite recently Morgans^{17a} published a third

From the Second Medical Service, Wilhelmina Gasthuis, Amsterdam, Holland

family in which there was suggestive evidence of a vertical spread of Gaucher's disease

4 In these instances of a 'vertical' transmission there was a direct continuity of the disease from one generation to the other. Only one example of "skipping" of a generation has been described in a paper by Anderson¹. This case is often quoted but the evidence offered does not seem convincing. Anderson observed four sisters with Gaucher's disease. The father and mother of these patients were found to be normal. The grandparents were not examined but it was reported that the paternal grandmother and two of her sisters had large abdomens and a yellowish brown discoloration of the skin and died of a common cause. The author did not go beyond suggesting the possibility that the grandmother and her sister might have had the disease. It would seem that this evidence is too scanty to warrant the far-reaching conclusions that have been drawn from it by some authors.*^{3 10}

5 The disease does not show a preference for either sex. Atkinson found among 108 cases in children, 50 males and 53 females, the sex of the other 5 cases was not given. Of the author's present series of 25 cases 14 were males and 11 females.

6 Marriage between relatives had not taken place in the ancestry of any of the reported cases of Gaucher's disease.

7 In the families in which Gaucher's disease occurred, there have been a number of normal siblings as well as affected cases.

8 Little is known of the offspring of patients with Gaucher's disease. Many of the cases die before they reach the reproductive age, others do not marry or if married have no children. Furthermore the incidence of abortions and of stillborn babies among the offspring of the reported cases of Gaucher's disease seems to be unusually high.

The survey of the author's cases confirms many of the points mentioned above. In addition it contains some data that may help to answer some of the questions that remained open so far.

DESCRIPTION OF FAMILIES OBSERVED BY THE AUTHOR

FAMILY A

H. U., a Jewish merchant, aged 49, was admitted in February, 1934. He had a typical clinical picture of Gaucher's disease and the diagnosis was established by pathologic examination of a liver biopsy. The patient's father committed suicide. No further information about him was available. His mother had died of old age. The family doctor assured us that he had never found a large liver or spleen in her. Two brothers and two sisters were examined and found to be normal. His wife was normal. She had had no abortions. They had two children, both died shortly after birth.

He is an example of a sporadic case, the only one of five siblings, originating from what appeared to be normal parents, who had Gaucher's disease. The fact that both his children died shortly after birth is probably significant.

FAMILY B (FIG. 1)

No medical information was available concerning the grandfather (I₂) of this family. He had been married twice. His first wife was reported to have died of apoplexy. Nothing was known about his second wife.

* In the paper by Bloem, Groen and Postma,³ it was said that Anderson's family suggested that the inheritance of Gaucher's disease might be of recessive character. Bloem and Postma now agree with the author that this statement should not have been made.

He had three children by his first marriage (II 1-3)

II 1 Female, unmarried, died in 1932, aged 75, of degenerative heart disease. She had been repeatedly hospitalized and no signs of Gaucher's disease were found on any occasion.

II 3 Female, still alive, 75 years of age when we examined her. She was found to suffer from gall stones and chronic cystitis but there was no evidence of Gaucher's disease. Her daughter (III 8) and two grand-daughters (IV 14-15) were examined and found to be normal.

II 2 Male, died in 1922, aged 62, of pulmonary embolism, after prostatectomy. He had once been told by a doctor that he had a big liver but the surgeon who operated on him had found nothing abnormal on an (admittedly superficial) examination of the abdomen. He had had no abnormal tendency to bleed. His wife had a mild diabetes but otherwise she was found to be normal. They had eight children (only seven of whom are represented in figure 1).

III 1 Female, 51 years old, was found to have a chronic cystitis but was otherwise normal, as were her three children (IV 1-3).

FIG 1 FAMILY B

III 2 Female, was known to her doctor to have a very large spleen and leukopenia. She suffered from nosebleeds. She died at the age of 36 from a severe postpartum hemorrhage on giving birth to her fifth child. This fifth child died of unknown cause one day after birth. The other four children were found to be normal. We feel that she very likely had Gaucher's disease.

III 3 Male, had frequent nosebleeds and hemorrhages after tooth extraction. No clinical signs of Gaucher's disease were found. Both his sons were normal.

III 4 Female, a typical case of Gaucher's disease, with a very large spleen and liver, symmetrical pigmentation of the legs, bone lesions and typical blood findings. She is unmarried.

III 5 Male, was found to have a slight glycosuria. He was otherwise normal, as were his two children.

III 6 Male, was found to be normal. He was married but had no children.

III 7 Male, married, was found to be normal, as was his only child, a daughter.

Not included in figure 1 is one other female, who was found to be normal, as was her only child, a son.

From the second marriage of I 2, also sprang three children.

II 4 Female, had five children. None of these could be personally examined but information obtained from family doctors and from hospital records revealed no evidence of Gaucher's disease in any of them.

II 5 Male, died suddenly at the age of 50, probably of coronary occlusion. Up till then he had always been a healthy man. His wife had had hypertension, she died of apoplexy. They had eleven children (III 14-24).

III 14 A schizophrenic who always refused medical examination. He died of suicide.

III 15, 16, 17 Died during the first days of life.

III 18 Male, unmarried, was found to be normal.

III 19 Female, found to have a very enlarged spleen and liver, this was confirmed by the surgeon when

she was operated on for gall stones. She had a tendency to bleed. In 1937 she died of subdural hematoma after an insignificant trauma of the head. Although we were not able to examine her personally, she very probably had Gaucher's disease. She was married but had no children.

III 20 Female, in 1936 she was reported by Bloem, Groen and Postma³ as having gall stones but being otherwise normal. Since then the patient has withdrawn her former refusal to be examined. The present author has had an opportunity to examine her. She had a definitely enlarged spleen but refused laboratory examinations. She suffers from nose bleeds. She has two children (*IV 16-17*). It was not possible to examine them but they are reported as being normal.

III 21-22 Were either abortions or dead children. This could not be ascertained with certainty.

III 23 Male, was found to have an enlarged spleen and liver, myopia and malar flushes, leukopenia and thrombopenia. He refused sternal puncture. We regard him as very likely a case of Gaucher's disease. He was unmarried.

III 24 Male, died at the age of 13, after splenectomy. The diagnosis of Gaucher's disease was made by pathologic examination of the spleen after operation.

III 6 Female, was normal, as were her six children (*III 25-30*). None of them had attained the marrying age.

FIG. 2. FAMILY C

The interesting points in this family tree are

1. Gaucher's disease appeared among the cousins of two families who were united only by one grandfather who had been married twice. Yet this man, who was the only link between the affected families, was apparently not a sufferer, nor were his two sons, who were half-brothers. However, these men (*II 2* and *II 5*) produced two and four children, respectively, who had the disease in a marked degree.

2. One of the sufferers who married (*III 2*) had one child that died shortly after birth. Furthermore, no less than 5 cases of early infantile death or stillbirth occurred in the offspring of *II 5*, although he was not a clinical case but only a transmitter.

3. A high proportion of the patients in this family were unmarried, or they were married but had no children. As a result, no cases of Gaucher's disease occurred in the fourth generation.

4. The normal members of the third generation all had normal children (if they had any). The few Gaucher patients who produced offspring had one stillborn baby and also some normal children.

FAMILY C (FIG. 2)

M S male, a 65 year old Jewish merchant, was admitted in November of 1934. Twenty years previously he had had a severe hemorrhage after an operation for hernia and subsequently had bleeding of a

marked degree with every wound or dental extraction. At the time of this operation no abnormalities were found on physical examination, but he now had a large spleen and liver, pingueculae, myopia, malar flushes, pigmentation and a typical blood picture of Gaucher's disease. Nothing was known about his father or mother. One brother died in an accident. Two others, aged 79 and 69, were examined and found to be normal. The patient had one daughter, who refused examination, and two sons. The elder son, aged 30, was found to have bronchitis, pigmentation, malar flushes, myopia, pingueculae, and an enlarged spleen. The younger son, aged 27, had the same signs but showed in addition early pigmentation of the legs and a typical blood picture. The older son was married but had no children. The younger son was unmarried. Neither of them had any complaints at the time of examination.

This family is remarkable because the diagnosis could be established in the father and two sons. The disease manifested itself in the father late in life. At the age of 45 nothing abnormal was found in this man. In his sons, however, the clinical picture was already fully developed at the age of 30 and 27 years, respectively.

FAMILY D

A 40-year old Jewish housewife, who was known for many years to have a swollen abdomen and pigmentation of the face with malar flush. On examination she was found to be a typical case of Gaucher's disease. Her father and mother, aged 62 and 60, respectively, were normal on physical examination. She had one sister who was also normal. She was married but she had no children. This patient was regarded as a so-called sporadic case of Gaucher's disease.

FAMILY E

Male, aged 25, non-Jewish, was admitted in 1934 with a typical picture of Gaucher's disease. Later, he was readmitted and the diagnosis was established by sternal puncture. Nothing was known about his parents, who were both dead. His sister, the only other living member of the family, was found to be normal. He married but he never had any children. He was another example of a sporadic case that produced no offspring.*

FAMILY F

Mrs. E. R. B., a Jewish married woman, born in 1890, had had her spleen removed in 1922. A diagnosis of Gaucher's disease was made on the specimen. She came under our observation in 1938 with a picture of cor pulmonale. The liver was enlarged. Gaucher's cells were found in the bone marrow. The patient's father had died of carcinoma of the rectum, her mother of apoplexy. Both had died in a hospital. No enlargement of the spleen or liver had been found in either of them. The patient had two sisters and one brother, who were all found to be normal. Her husband was also normal as were her two children, 25 and 19 years old, respectively. She had had no abortions. She was considered to be a sporadic case of Gaucher's disease.

FAMILY G (FIG. 3)

Mr. Fa., a Jewish lawyer, born in 1901, was examined in 1937. He was found to have an enlarged spleen and liver, pigmentation and areas of destruction in the bones. Gaucher's cells were found in the bone marrow. Curiously enough, this patient had also harbored another rare disease, namely, an islet cell tumor of the pancreas. The patient's father had died of arteriosclerosis, his mother of kidney trouble. One sister has gall stones. She showed no evidence of Gaucher's disease on clinical examination. One brother is suffering from Gaucher's disease. The diagnosis was established on clinical grounds and verified by sternal puncture elsewhere. A second brother is reported as suffering from a slightly enlarged spleen and a moderate secondary anemia. A third brother died when 5 months old. The patient was unmarried.

This patient further told us that a cousin on the maternal side had had his spleen removed, a diagnosis of Gaucher's disease had been established by pathologic examination of the specimen. We have not been able to verify this statement.

* The cases described so far are the same as those in the publication by Bloem, Groen and Postma.³

FAMILY H

A 30 year old Jewish business man, born in 1908, was examined in 1938. He was a typical case of Gaucher's disease, with enlargement of the liver and spleen, hemorrhagic diathesis, and involvement of the bones. Gaucher's cells were found in the sternal marrow. His mother was examined and found to be normal. His father had died from a heart attack. He was the only child. He was married to a normal wife. He had one child, a boy, 5 years old, who was found to be normal. This man was regarded as a sporadic case of Gaucher's disease.

FIG 3 FAMILY G

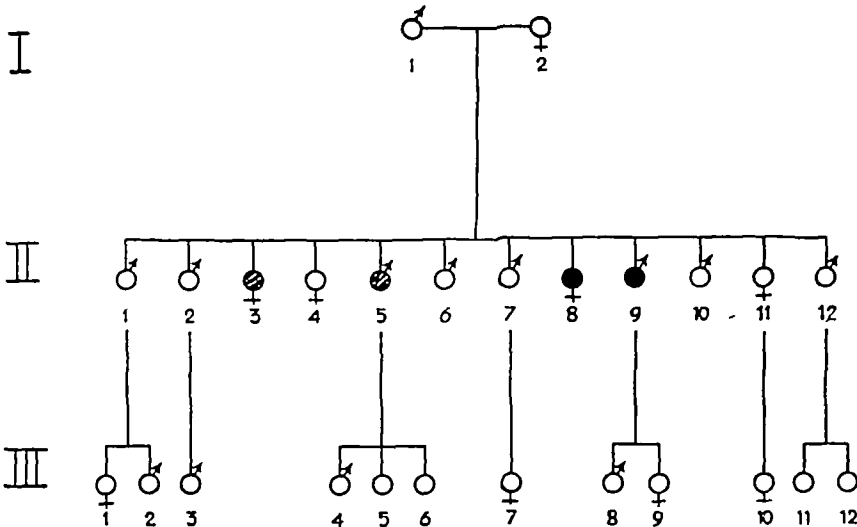

FIG 4 FAMILY I

FAMILY I (FIG 4)

I 1 A retired Jewish butcher who died aged 82, had a chronic bronchitis and inguinal hernia. No signs of Gaucher's disease were found in him during his life. His wife had died of carcinoma of the uterus. An internist who had examined her several times told us that he had never found a large spleen or any other abnormalities which could have indicated the presence of Gaucher's disease. They had 12 children.

II 1 Male 55 years old, was found to be normal, as were his two children 19 and 17 years old, respectively.

II 2 Male 8 years old died of carcinoma of the colon. No evidence of Gaucher's disease had been observed in this man by the surgeon who operated on him. His only child, a son, was examined and found to be normal.

II 3 Female died in 1927 28 years old, after an operation for carcinoma of the ovary. No evidence of Gaucher's disease was found but the family had noticed that she had the same malar flushes as the sib-

lings II 5, II 8 and II 9. She was myopic. She died on the day of operation, possibly of an internal hemorrhage. No further evidence could be obtained and the presence of Gaucher's disease in her case must be regarded as suspicious. She was married but had no children.

II 4. Female, unmarried, was not on speaking terms with any other member of the family. She could not be traced for examination.

II 5. Male. He emigrated from Holland to the U.S.A. at an early age. He could not be examined. He was said to suffer from nose bleeds, and he had the same peculiar malar flushes as the affected siblings. His wife was apparently normal. Their first baby was stillborn. After this his wife had two abortions. We cannot go beyond suspecting Gaucher's disease in this case.

II 6. A boy, died at the age of 2 years.

II 7. Male, was examined and found to be normal except for an ulcer of the duodenum. His only child, a daughter, 7 years old, was normal.

II 8. Female, was first seen by us in 1938. She complained of severe sciatica. She was found to have an enlarged spleen and liver, and lesions in the lumbar vertebrae, the sacral and the iliac bones. She had malar flushes, myopia and a tendency to bleed. Blood picture showed leukopenia, hypochromic anemia and thrombopenia. Typical Gaucher's cells were found in the sternal marrow. In addition, she was found to have gall stones. Later she developed pulmonary tuberculosis. She was unmarried.

II 9. Male, who had never been examined previously. On examination he was found to have pingueculae, pigmentation of the skin, malar flushes, myopia and an enlarged liver and spleen. One year before examination he had suffered from sciatica but this had disappeared without treatment. Gaucher's cells were found in the sternal marrow. His two children (III 8-9) were found to be normal.

II 10. A boy, died at the age of 4 months.

II 11. Female, was found to be normal, as was her only child.

II 12. Male, had vague abdominal complaints, no clinical signs of Gaucher's disease were found. His wife had had two abortions. There were no children.

This family presented 'horizontal spread'. In the second generation there were two proven cases of Gaucher's disease and two individuals who could not be examined but in whom there was a justified suspicion of the disease. Neither of the parents of these cases had shown clinical evidence of Gaucher's disease. All but one of the normal members of the second generation, who had produced children, had a normal offspring. This one exception was an apparently normal man (II 12) whose wife had two abortions. One of the cases of Gaucher's disease in this family had normal children. One of the suspected individuals had produced no live children but one stillborn baby and two abortions. The 'reproduction balance' in this family was: From 8 normal individuals in the second generation sprang 5 normal children and 2 abortions, from 2 patients plus 2 suspected cases sprang 2 normal children, one stillborn baby and two abortions, so that in the third generation there was no case of Gaucher's disease left.

FAMILY J (FIG 5)

Two Jewish girls, sisters (A X and E X) born in 1913 and 1927, respectively, were examined in 1939. A X had an enlarged spleen and liver, malar flushes, hypochromic anemia, leukopenia, thrombopenia, hemorrhagic diathesis, bone involvement, and typical pigmentation. Typical Gaucher's cells were found in the marrow.

E X underwent splenectomy in 1930. Gaucher's cells were identified in the spleen and kerosin was isolated from the specimen. She had swelling of the liver, transient pigmentation, malar flushes, bone involvement, anemia, thrombopenia, but no leukopenia. Gaucher's cells were present in the bone marrow.

The mother of these girls (I 2) was found to be normal on clinical examination. Her sternal marrow was normal. The father (I 1) had bilateral pingueculae and a few scattered gray spots on the skin of the legs. His liver and spleen were not enlarged. The blood picture was also normal. In the sternal marrow,

a few abnormal cells were found that might have been called reticulum cells or stem cells but the faintly-stained protoplasm was nonhomogeneous in character, and resembled in its structure compressed tissue paper. It was felt that these were actually small Gaucher cells and a diagnosis of subclinical Gaucher's disease was established. No other case was found in the family, although three brothers of the patients were examined clinically and by sternal puncture.

This then was a family in which, what seemed to be at first the sporadic occurrence of Gaucher's disease in two sisters could be explained by unmasking the father as a subclinical case or an almost normal 'carrier'. It seems significant that whereas this man had no clinical evidence of the disease at the age of 39, both his daughters were already affected as children and showed signs of steady progress of the disease.*

FIG 5 FAMILY J

DISCUSSION

The familial occurrence of Gaucher's disease without clear-cut transmission in a vertical line from parents to children has puzzled many observers. It has given rise to peculiar theories which challenge the established laws of heredity. Rowland,¹⁶ for instance, writes: "As Gaucher's disease is a constitutional anomaly, that is, a mutation in the human species that follows Mendelian law, it is sometimes inherited recessively and sometimes shows dominant characteristics."

The concept of Gaucher's disease as a mutation is founded on its being a congenital anomaly of a sudden occurrence. However, a mutation, once it has established itself, would be expected to be transmitted as a constant entity from parents to offspring. Actually, very few instances have been observed in which a patient with Gaucher's disease has transmitted the disease to his offspring. This is, in the first place, due to the fact that many cases of Gaucher's disease occur in children who die before they reach the reproductive age. Among the cases that reach maturity, a number remain unmarried and among the married patients there is a remarkably high incidence of abortion, stillbirth, and of children who die shortly after birth. For the rest, a certain number of normal children have been observed among the offspring of patients with Gaucher's disease. This, however, cannot be an argument against the hereditary character since, even if a disease is dominant, it will affect only 50 per cent of the offspring. All these points, evident from the literature, were confirmed by the genetic data here presented.

* The cases belonging to the families F to J have been described by Gerrer and Groen.⁹

Obviously, Gaucher's disease has a tendency to extinguish itself. If the disease is present at birth, death seems to result within a year.¹² If it begins in childhood, death occurs in the first or second decade. In young adults the disease can be compatible with life for many years, but the affected offspring die before or shortly after birth and only the unaffected children survive. The only cases, therefore, which are left to study the transmission of Gaucher's disease from a parent to his children are those in whom the disease manifests itself late in life.

An example of this situation is furnished by Family C. The father was a very mild case. When he was 45, he apparently had no clinical evidence of Gaucher's disease and the abnormality was discovered only when he was 65 years old. In his case, the disease had been so mild that it had not interfered with his reaching an advanced age and it had apparently permitted transmission to two children who survived. The transmission in this family was of a simple dominant type. It is significant that whereas the father developed clinical manifestations of the disease at the age of 65, both sons had already showed a marked enlargement of the spleen at the ages of 30 and 27, respectively. Apparently the disease became more serious in the second generation.* This suggests that the frequent occurrence of abortion and stillbirth in the offspring of patients with Gaucher's disease may be due to the fact that the disease makes its appearance in the affected children at an age so early that it has a lethal effect, either during the intrauterine development or shortly thereafter.

Family B shows another interesting aspect of the hereditary mechanism. Here the disease was present in a number of *cousins* of the same generation. It seems an inevitable conclusion that the affected members of this family inherited their disease from the only ancestor they had in common. It so happened that they sprang from different grandmothers but from the same grandfather. This grandfather, therefore, must have had the genes abnormality.

We are forced to conclude that he transmitted the disease to his sons, who fathered the affected siblings. It is interesting that neither this grandfather nor his two sons exhibited any sign of Gaucher's disease during life, and as we have just concluded that the disease is dominant, the only explanation left is that Gaucher's disease might be present in a carrier individual in a mild, subclinical form. Furthermore one gets the impression from the data available that after every transmission the disease increases in severity until after two (or possibly more) generations, the anomaly is so severe that it manifests itself clinically. From then onwards, it would depend on the severity already reached whether one more affected individual can be produced which can still survive. In the end, however, the mutation becomes incompatible with reproduction or life, and thereby extinguishes itself. The high number of miscarriages, stillbirths and early deaths among the members of Family B is in harmony with this hypothesis.

* This statement was strikingly demonstrated in the study of a recent case of severe Gaucher's disease in a boy of 16. His parents were apparently in excellent health, but examination of both of them revealed splenomegaly in the mother, both by palpation and by x-ray examination. The blood showed slight leukopenia, and the sternal marrow aspiration showed numerous Gaucher cells. X-rays of the bones were negative. This woman must be defined as a carrier since she had always been well and at the age of 4- appeared to be in excellent physical condition. *Editor*

A proof for this concept could be found in Family J. Here two girls were affected at an early age. The parents were seemingly normal, but the discovery of early Gaucher's cells in the bone marrow of the father unmasked him as a 'subclinical case' who acted as a carrier of Gaucher's disease. In Family I this proof could not be furnished because none of the parents was alive when the family was studied.

Several further points emerge from this hypothesis. It is possible, e.g., that what are commonly regarded as so-called 'sporadic' cases of Gaucher's disease may be individuals who acquired the disease straightway in a serious degree as the first mutation. It is also possible however, that many of these only manifest a disturbance which was already present in a subclinical degree in one of their parents who acted as a carrier.

Apart from the peculiarity that the disease tends to increase in severity in succeeding generations, the mechanism of transmission in Gaucher's disease appears to be following the genetic rules for one simple dominant trait. Strictly speaking, one would expect that in that case 50 per cent of the offspring would be affected. Actually, the number of siblings in the families described above is too small to decide this point. The patient in Family A had two children, both of whom died shortly after birth and were presumably affected. Two of the three siblings of the patient in Family C had the disease. In these two families the incidence of Gaucher's disease among the offspring seemed higher than 50 per cent. In Family I about half of the patient's offspring were either abortions or stillborns. In the Families B and J, however, the incidence of affected individuals among the offspring of the patients was less than one-half of the siblings and the patients F and H had one child each, neither of whom were affected. The total 'reproductive balance' of all the families was about as follows. Of 18 adult patients (including the two suspected cases from Family I) 9 were unmarried and 4 were married but had no children, giving an incidence of infertility of 72 per cent. The remaining 5 patients produced 2 abortions, 4 stillborn babies, 4 individuals with Gaucher's disease and 16 normal individuals. The incidence of affected or stunted individuals among the offspring of the Gaucher cases was therefore almost 40 per cent. A theoretic figure of 50 per cent, to be expected if Gaucher's disease were inherited as a simple dominant trait, might be reached if a larger number of families were investigated but in view of the high incidence of infertility it is doubtful if this figure would actually give a true picture of the situation. Among 15 normal members of the same generation as the patients, who reached the reproductive age and of whom we examined the offspring we found only 2 who were unmarried and 2 who were married but had no children. The incidence of infertility among this control group was 26 per cent. The remaining 9 persons produced 2 abortions, no stillborn babies, no cases of Gaucher's disease and 20 normal individuals. The incidence of stunted individuals among this group was only 9 per cent.

One of the important results of the present investigation is the demonstration of the subclinical or 'carrier' state in the father of Family J by examination of the sternal marrow. This makes it imperative to use this technic in every genetic investigation of Gaucher's disease. Unfortunately shortly after this was realized the German invasion of the Netherlands occurred and almost all of the Jewish persons

described in this paper were seized and deported to Poland where they were exterminated. As a result the author was unable to perform sternal punctures on the seemingly normal individuals in these families. It is hoped that others who have an opportunity to carry out similar investigations will complement their clinical studies with marrow puncture. Whether healthy individuals in whom early Gaucher cells are found by this technic should best be named "subclinical cases" or 'carriers' is a matter of philosophy.

The substrate of Gaucher's disease is a disturbance in the metabolism of a special lipid, kersasin. It is commonly assumed that this lipid is a product of metabolism somewhere in the body which cannot be destroyed by the lack of some enzyme and is consequently stored in the reticulum cells. Another possibility is that there is an increased production of the substance inside these cells themselves.¹⁰ However this may be, the seriousness of the disease depends on the total excess of kersasin that is present in the body. A small quantity of this substance inside the reticulum cells of spleen, liver, bone marrow, etc. does not result in appreciable harm. It is only when excessive amounts are present that the liver and spleen become enlarged, destruction of bone marrow occurs and a serious condition arises. It seems a likely supposition that Gaucher's disease is due to a deficiency of some specific enzyme. The seriousness of the disease would depend upon whether the enzyme is only somewhat diminished in quantity or totally lacking. It seems that as the disease is transmitted, the quantity of this hypothetical enzyme diminishes in the next individual. This concept is in harmony with what we see in many other hereditary diseases, where what is merely an innocent trait in a parent becomes an actual disease in the offspring.¹³ Gaucher's disease is also another example indicating that hereditary diseases can occur in varying degrees of severity just as acquired diseases, a concept which many physicians still realize insufficiently.

Finally, attention should be drawn to the frequent occurrence of cholelithiasis and mild diabetes in the families with Gaucher's disease, both in the affected and in the normal siblings.

SUMMARY

The author reviews the literature of the familial incidence of Gaucher's disease. Almost all the familial cases which have been described occurred in the members of one generation (siblings or cousins) only. To these cases reported in the literature the author adds 25, of which 4 were 'sporadic' cases. The other 21 cases occurred in 6 families. The pedigrees of these families are presented. After an analysis of the available data the author presents the following hypothesis for the hereditary mechanism in these families.

Gaucher's disease is a mutation which, once established, is transmitted as a simple dominant hereditary trait. In the affected individuals this trait gives rise to a disturbance of lipid metabolism which results in the accumulation of kersasin in the reticulum cells throughout the body. The severity of the disease may vary considerably. It can be present in such a slight degree that the amount of kersasin accumulated during life is too small to give rise to clinical manifestations. In other cases the progression may be so slow that the disease becomes manifest only in

old age, provided the affected individual lives long enough. In these "subclinical cases," a diagnosis of Gaucher's disease can sometimes be made by the detection of 'early Gaucher cells' in the sternal marrow. Individuals thus affected suffer from Gaucher's trait rather than from the actual disease. However, they can transmit the disease to 50 per cent of their offspring, and thus function as (almost) normal carriers. In the family trees presented, it appeared that the disease tended to become more severe in every succeeding generation until after two or three generations it became clinically manifest in the affected individuals early in life. In the next generation it would then establish itself during fetal life so as to give rise to abortion, stillbirth or early death of the affected infant. In this way the mutation extinguishes itself, by permitting only the unaffected offspring of the affected individuals to persist. As a practical conclusion it is urged that a sternal marrow examination be included in every genetic investigation of Gaucher's disease as the best method available at present for the detection of subclinical cases or 'carriers'.

STUDIES CONCERNING THE PATHOGENESIS OF GAUCHER'S DISEASE

By BERTHA OTTENSTEIN, Ph D , GERHARD SCHMIDT, M D , AND
S J THANNHAUSER, M D

IN 1882 Charles Ernst Gaucher¹ described as 'epithelioma primitif de la rate' the disease which now bears his name. In his case he found the splenic pulp entirely replaced by large cells and attributed this condition to a primary tumorous growth, epithelioma of the spleen. Collier² (1895) in England, and Picou and Ramond³ in France (1896) also regarded the condition as neoplastic. Bovaird⁴ (1900), reporting the first case in this country, called attention to the simultaneous appearance of these large cells in the liver as well as in the spleen and lymph nodes. He had commented on the familial character of the disease. In contrast to the current view that the disease was of tumorous nature, he believed that an unknown toxin caused hyperplasia of spleen, liver, and lymph nodes. Brill, Mandlebaum and Libman⁵ (1905) were the first to point out that the cells which characterized the disease were found, not only in the liver, spleen and lymph nodes, but appeared simultaneously in different parts of the skeleton. These authors suggested (1913) the name, 'Gaucher's disease,' to avoid the misleading term 'primary idiopathic spleno-megaly.' Schlagenhauser⁶ (1906) considered that the condition was a systemic disease of the lymphhemapoietic tissue.

H. Lieb^{7, 8} (1924, 1925), in association with Epstein and Lorenz,⁹ isolated the substance which characterized the Gaucher cells and identified this substance as a cerebroside, namely kersasin. It was believed that kersasin, a galactosidocerebroside, was a constituent only of brain tissue and not of visceral organs. L. Pick¹⁰ assumed that kersasin originated as a result of a general disturbance of intermediary lipid metabolism, accumulated in the blood, and was secondarily deposited and stored in the reticulum cells of the involved organs. He characterized Gaucher's disease 'not as a reticulo-endothelial, reticular cell or histiocytomatotic disease, but as a histiocytic disease comparable to histiocytic storage as observed in vital staining or cholesterol feeding of animals with, however, elective participation of certain histiocytic forms.'

In contrast to the conception of L. Pick,¹⁰ S. J. Thannhauser and co-workers¹¹ demonstrated that normal serum or serum of patients with Gaucher's disease did not contain measurable amounts of cerebroside. This observation was subsequently confirmed by Dvoracek and Pest,¹² and Bruckner.¹³ Since cerebroside is not present in the serum of Gaucher's disease, Thannhauser¹⁴ concluded that cerebroside does not originate as a result of a general disturbance of the intermediary lipid metabolism but are synthesized and stored in the cells where they are found, i.e., in the Gaucher cells. This explanation of the pathologic formation of cerebroside places the metabolic disorder within the reticulum cells and histiocytes.

From the Research Laboratories of the Boston Dispensary and the Joseph H. Pratt Diagnostic Hospital and the Department of Medicine, Tufts College Medical School, Boston.

This study was aided by grants from the Rockefeller Foundation, the Godfrey M. Hays Fund, the Vingham Associates Fund and the Charlton Fund.

An imbalance of the intracellular enzymes concerned with cerebroside formation and disintegration is assumed to be the fundamental defect in Gaucher's disease. Similarly in Niemann-Pick's disease an enzymatic intracellular disturbance presumably leads to increased sphingomyelin formation. An enzymatic deviation of the intracellular lipid metabolism is therefore considered as the etiology of these disorders.

This view is supported by the experiments of Thannhauser and Reichel¹⁵ and by Ottenstein, Schmidt and Thannhauser,¹⁶ who demonstrated that cerebrosidease is an intracellular enzyme which cannot be extracted from the tissue.

A further support for the view that the cerebroside in Gaucher's disease is synthesized and stored in the cells where they are found is evident from the discovery of an hitherto unknown group of cerebroside occurring exclusively in the Gaucher cells, namely a glucosidocerebroside (Halliday, Deuel, Tragerman and Ward¹⁷ and Aghion¹⁸). In glucosidocerebroside, the carbohydrate group is glucose and not galactose as in kerafin. The findings of Halliday and co-workers have been confirmed by Klenk,¹⁹ Danielson, Hall and Everett²⁰ and by Polonovski.²¹

The question arises whether in Gaucher's disease an abnormal cerebroside, i.e., glucosidocerebroside, is formed exclusively or whether in different individual cases the type of cerebroside may vary and both cerebroside, galactosido- (kerafin) and glucosidocerebroside may be present together.

The purpose of this paper is an attempt to decide this question by a method that permits quantitative partition of cerebroside into galactosido- and glucosidocerebroside. This method is described in the present paper and applied to the analysis of organs of different cases of Gaucher's disease. It will be demonstrated that in individual cases the organs vary in the amount and type of cerebroside present.

Our investigations were carried out with the additional purpose of clarifying another question regarding the pathogenesis of Gaucher's disease. It is known that normal red blood cells contain a small amount of cerebroside. It might be inferred that the increase of cerebroside in Gaucher organs may have resulted from a primary accumulation of cerebroside in the red blood cells. Deposition of this material in the organs in Gaucher's disease could occur even though the serum did not contain appreciable amounts of this lipid.

It will be shown by the chemical analysis of red blood cells from normal individuals and from patients with Gaucher's disease that the cerebroside present are quantitatively and qualitatively the same. These findings seem to support the conception of Thannhauser and co-workers¹¹⁻¹⁴ that the large amount of cerebroside present in the organs involved in Gaucher's disease is due to their synthesis and storage in the cells where they are found.

MICRODETERMINATION OF CEREBROSIDES IN RED BLOOD CELLS AND IN TISSUES

PRINCIPLE

The characteristic group which distinguishes the cerebroside from most of the other lipids is their carbohydrate component. Since the carbohydrate group can be liberated quantitatively from the cerebroside by acid hydrolysis the estimation of the free sugars in hydrolysate total of the lipid fraction is at present the basis of all analytical procedures for the quantitative determination of cerebroside.

(Brückner,^{13a, b} Halliday, Deuel, Tragerman and Ward,¹⁷ Aghion,¹⁸ Klenk,¹⁹ Danielson, Hall and Everett,² Polonovski,²⁰ and Brand and Sperry²²

The conversion of the results of the sugar determination into cerebroside values, however, requires the application of certain precautions

1 The crude alcoholic lipid extract contains in addition to the cerebroside noticeable amounts of nonlipid carbohydrates. The removal of the contaminating carbohydrates is achieved by extracting the final solutions of the lipids in chloroform repeatedly with an aqueous solution of trichloroacetic acid

2 It was found by Brand and Sperry,²² as well as by us, that the customary hydrolysis of the lipids with sulfuric acid entails considerable losses due to destruction of carbohydrates, but that hydrochloric acid under certain conditions permits the quantitative recovery of the sugars

3 It has recently been shown that the carbohydrate component of the cerebroside is not exclusively galactose, but at least under certain conditions in Gaucher's disease,¹⁷⁻²¹ a mixture of galactose and glucose is present. Since equal amounts of galactose and glucose have different reduction values, the correct conversion factor can only be established by separate determination of glucose and galactose in the hydrolysate. Our procedure for the quantitative partition of the sugars into galactose and glucose is based on the removal of the latter by yeast fermentation

PROCEDURE

Extraction The amount of material required for the determination varies according to its cerebroside content. The following amounts of various tissues have been found to be suitable for the determinations of cerebroside: 10 Gm. of washed red blood cells corresponding to approximately 40 cc. of oxalated blood, 5 to 10 Gm. of wet brain, 20 Gm. of visceral organs, 50 mg. of crystallized cerebroside mixtures. For the quantitative extraction of cerebroside the material is homogenized in the Waring Blendor with 20 to 30 volumes of 95 per cent alcohol. The suspension is refluxed for 30 minutes and filtered while still hot. The residue is re-extracted by refluxing with the same amount of 95 per cent alcohol. The combined extracts are evaporated to dryness under reduced pressure. The oily residue is refluxed with a mixture of 4 volumes of chloroform and 1 volume of ethanol, filtered while still hot and washed with the chloroform ethanol mixture.

Removal of nonlipid carbohydrates The combined extracts and washings are transferred to a 250 cc. centrifuge tube and stirred mechanically with four volumes of 2 per cent trichloroacetic acid for ten minutes. After separation of the emulsion by centrifugation the aqueous top layer is siphoned off and discarded. The extraction with trichloroacetic acid is repeated at least twice until a microdetermination of the sugar (Somogyi²³) in an aliquot of the aqueous layer shows the absence of reducing carbohydrates.

Hydrolysis The chloroform ethanol extract is transferred to a 60 cc. centrifuge tube and brought to dryness at room temperature by an air current which is bubbled through the solution. The residue is suspended in 15 cc. of an aqueous, 1 N, solution of hydrochloric acid by means of a glass rod. The hydrolysis is carried out on a boiling water bath for sixty minutes. The centrifuge tube is covered with a loosely fitting glass bulb. The cooled hydrolysate is brought to a volume of 25 cc., sharply centrifuged and filtered.

Removal of free acid by Amberlite Prior to the sugar determination, the free acid is removed from the hydrolysate by absorption on Amberlite (analytical grade IR 4B). (The neutralization cannot be carried out by the addition of alkali since the presence of salts interferes with the subsequent fermentation.) For this purpose an aliquot of the hydrolysate is stirred mechanically with the resin (2 Gm. per 10 cc. hydrolysate*), for twenty minutes until the color of congo red paper is not changed by a drop of the supernatant.

All controls are brought to a volume of 10 cc. and incubated for three hours at room temperature. After centrifugation, the reduction is determined in an aliquot of the supernatant according to Somogyi.²³ The mixture is brought to a volume of 10 cc. in a volumetric flask and fermented at room temperature for 3 hours. After centrifugation, the nonfermentable sugar is determined in 5 cc. of the supernatant according to Somogyi.²³

* Control experiments with known glucose solutions have shown that analytical grade Amberlite does not absorb any glucose.

In a second aliquot of 4 cc of the Amberlite supernatant the total carbohydrates are determined according to Somogyi without fermentation

Calculation The titration value F obtained in the fermented aliquot represents galactose and is accordingly multiplied by the factor 0.20 in order to obtain the amount of galactose in milligrams. The difference between F and between the titration value T obtained with the unfermented aliquot represents glucose and is multiplied by the factor 0.14 (Somogyi)

In order to calculate the amount of cerebrosides the galactose, respectively the glucose values are multiplied by the factor 4.6

Determination of galactose and of total carbohydrates An aliquot of 8 cc of the Amberlite supernatant is mixed with 1 cc of a 10 per cent suspension of fresh baker's yeast* (Fleischmann)

Analyses of the cerebrosides in normal serum and Gaucher serum showed

Normal serum		Gaucher serum	
Galactosidocerebrosides	Glucosidocerebrosides	Galactosidocerebrosides	Glucosidocerebrosides
Traces	0	Traces	0

The analyses were made on 30 cc samples of serum of three normal individuals, as well as on 30 cc samples of two patients with Gaucher's disease (case Ke, 14 years old and case Le, 24 years old)

These figures confirm the analytical findings of Thannhauser and co-workers,¹¹ Brückner,^{13a} Dovracek and Pesta¹² indicating that the serum of Gaucher's disease does not contain measurable amounts of cerebrosides

TABLE 1—ANALYSIS OF RED BLOOD CELLS IN NORMAL INDIVIDUALS AND PATIENTS WITH GAUCHER'S DISEASE

Normal R B C Per cent of desiccator dried weight		Gaucher R B C Per cent of desiccator dried weight	
Galactosidocerebrosides	Glucosidocerebrosides	Galactosidocerebrosides	Glucosidocerebrosides
0.189	0	0.200 (case Ke) 0.220 (case Le)	0 (case Ke) 0 (case Le)

The analyses of red blood cells, washed with saline, were made in three normal individuals from an average of 9.8 Gm of dried material, the samples being dried in a desiccator at room temperature

The analyses of Gaucher red blood cells, washed with saline, were made in case Ke, 14 years old, on 7.7 Gm dried substance, in case Le, 24 years old, on 8.6 Gm dried substance

The figures in table 1 demonstrate that the content and the type of cerebroside in the red cells of Gaucher's disease do not differ from those found in normal red blood cells. It is important to note that both in the normal and Gaucher's disease, only galactosidocerebrosides were found in the red cells even when glucosidocerebrosides were accumulated in the Gaucher cells of the spleen, as in case Ke (corresponding to Case 1 in table 2)

The organs of cases 1 and 2 were from children of 6 to 10 years of age, cases 3 and

* With each series of analyses the following additional control determinations are carried out: (a) 1 cc of the washed yeast suspension is mixed with water; (b) 1 cc of the washed yeast suspension is mixed with a known amount of glucose; (c) 1 cc of the washed yeast suspension is mixed with a known amount of galactose

TABLE 2.—ANALYSES OF SPLEENS IN 4 CASES OF GAUCHER'S DISEASE BY ISOLATION

Crystalline cerebrosidcs from Gaucher spleen	Total cerebrosidcs in per cent of dry weight	Galactosido-cerebrosidcs in per cent of dry weight	Glucosidocercbrosidcs in per cent of dry weight	Ratio galactocercbrosidcs glucosidocercbrosidcs

* Cerebrosidcs in the brain of a one day old child

4 from adults In cases 1, 2, and 3 the cerebrosidcs were isolated in crystalline form and the analyses were made for galactosido- and glucosidocerebrosidcs

In case 4* the galactosidocerebrosidcs and glucosidocerebrosidcs were determined

* We are indebted to Dr Karl Singer, Michael Reese Hospital, Chicago, for sending this spleen of an adult Gaucher's disease

directly in the organ as well as after isolation of the crystalline cerebroside mixture

The analytic figures of normal human and animal spleen are charted in table 2

The figures in table 3 and table 4 demonstrate that even in the organs of siblings with generalized infantile Gaucher's disease the amount and the type of galactosido- and glucosidocerebrosides may vary greatly. The intracellular metabolic disorder in Gaucher's disease is thus not solely confined to the formation of an abnormal glucosidocerebroside, since in one of the examined siblings, mainly galactosidocerebrosides and in the other sibling galactosido- and glucosidocerebrosides in varying amounts were found in the organs

DISCUSSION

The above findings (table 2) demonstrate that the spleen of two children with Gaucher's disease contained glucosidocerebrosides almost exclusively, thus confirming the observations of Halliday, Deuel, Tragerman and Ward,¹⁷ Aghion,¹⁸ Klenk,¹⁹ Danielson, Hall and Everett,²⁰ and Polonovski.²¹

In cases 3 and 4, however, both galactosido- and glucosidocerebrosides were present. These findings are the first demonstration that both types of cerebroside may be increased in the organs of patients with Gaucher's disease.

The fact that the galactosidocerebrosides and the glucosidocerebrosides may be found together indicates that the increased formation of cerebroside within the Gaucher cells is not a complete deviation from the synthesis of the normal galactosidocerebrosides. The occurrence of the abnormal glucosidocerebrosides exclusively within the Gaucher cells lends support to the theory that these cerebroside are built and stored in the Gaucher cells.

The alternating occurrence of galacto- and glucosidocerebrosides is especially evident in the cases of 2 siblings with generalized infantile Gaucher's disease. In the 7 months old infant, mainly galactosidocerebrosides were present with only

SUMMARY

1 The serum of normal individuals and of patients with Gaucher's disease does not contain cerebroside in measurable amounts. Cerebroside in Gaucher's disease are increased only in those organs containing abundant numbers of cells characteristic of the disease.

2 Normal red blood cells contain approximately 0.19 per cent cerebroside. The cerebroside in red blood cells is a galactosidocerebroside.

3 Red blood cells in Gaucher's disease do not differ quantitatively and qualitatively in their cerebroside content from the red blood cells of normal individuals.

4 In four different cases of Gaucher's disease separate determinations of splenic galactosido- and glucosidocerebroside were made. The spleen of two adults showed mainly glucosidocerebroside and only traces of galactosidocerebroside, while the analysis of the spleen of two other adults showed that galactosido- as well as glucosidocerebroside may be accumulated simultaneously in Gaucher cells. These findings are of importance, since it is demonstrated that the deviation of the cerebroside metabolism in Gaucher cells not only results in the formation of an abnormal glucosidocerebroside, but also may lead to the increased formation of the normal galactosidocerebroside, *kerasin*. It is demonstrated that the relative proportions of galactosido- and glucosidocerebroside in Gaucher cells may differ considerably in individual cases.

5 The organs of infantile siblings with generalized infantile Gaucher's disease were analyzed. The organs of one infant showed mainly galactosidocerebroside while in the organs of the other sibling both kinds of cerebroside, glucosido- as well as galactosidocerebroside, were present.

6 The findings reported in this paper lend support to the theory that Gaucher's disease is the result of a deviation of the intracellular metabolism of reticulum cells and histiocytes. The cerebroside is not transported by the serum or by the red blood cells and secondarily deposited in the cells involved, but is formed and stored in the reticulum cells and histiocytes where they are found.

EFFECTS OF X-RAY ON LYMPHOID AND HEMOPOIETIC TISSUES OF ALBINO MICE

By G. BRECHER, M.D., K. M. ENDICOTT, M.D., H. GUMP, A.B., AND
H. P. BRAUNER

HEINEKE,¹ investigating effects of x-rays on internal organs, found the lymphoid tissues peculiarly susceptible to irradiation. This observation suggested the possibility of studying the function of the lymphoid apparatus by observing animals deprived of their lymphoid tissue by means of selective injury by x-ray.² For this purpose it is necessary to suppress lymphopoiesis without interfering with other bodily functions of the experimental animals used. Permanent destruction of the lymphoid tissues cannot be accomplished without deleterious effects upon other organs, as shown by Hughes and Job.³ However, with a single whole body irradiation of 400 r, Henshaw⁴ produced in albino mice marked temporary lymphopenia accompanied by only slight neutropenia and anemia. The dosage used by Henshaw thus appeared to produce the highly selective damage of lymphoid tissues necessary for functional studies of this system. The present study was undertaken to furnish further details of the selectivity of radiation injury produced with this dosage by measuring the initial damage to all blood-forming tissues and the reticulo-endothelial system, the extent and duration of the suppression of their activity, and the rate of their recovery.

MATERIAL AND METHODS

Inbred female mice of the CFW strain, 2 months old, were given single whole body radiation of 400 r as measured in air with the Victoreen ionization chamber (186 KV 20 Milliamps, at 50 cm with 0.25 mm copper and 0.55 mm aluminum filters, for 6.24 minutes). All animals survived the period of the experiment without obvious illness. The animals were examined in groups of six on the 1st, 2nd, 4th, 7th, 10th, 14th, 21st and 28th day after irradiation. On three mice of each group of six, peripheral white blood cell counts and differential counts were done, as well as hemoglobin determination with the Evelyn photoelectric colorimeter, standardized by Van Slyke's method. On the remaining three mice of each group the peripheral red blood cells and reticulocytes were counted and the hematocrit values determined using Van Allen's method. All six mice were then killed with chloroform. The animals were weighed and autopsies were performed. The superficial cervical lymph nodes, thymus, liver and spleen were weighed and fixed in Helly's fluid. Kidneys, heart and lungs were also fixed in Helly's fluid, but not weighed. The gastrointestinal and genital tracts were inspected for gross lesions. The brain and cord were not examined. Paraffin sections were prepared and stained routinely with hemalum azure eosinate and with hematoxylin-eosin. In addition the Rio-Hortega Foot silver reticulum stain, the Berlin blue reaction for iron, and the periodic acid-leukofuchsin stain⁹ were used extensively on sections of the lymph nodes, spleen and thymus. Frozen sections of lymph nodes for the demonstration of fat were prepared in a few instances.

The bone marrow of one femur was used for the preparation of marrow smears.⁵ Smears were routinely stained with Giemsa and frequently also with the peroxidase stain.⁶ The other femur and several thoracic vertebrae were fixed in formalin and decalcified. Paraffin sections of them stained by van Gieson's method. Photomicrographs of the marrow of the epiphysis, metaphysis and shaft of the femur and of one vertebra were then prepared. Each photomicrograph was superimposed upon a cross ruled transparent grill. The

number of squares of available marrow space and the number occupied by cellular marrow were each counted. The cellularity of the marrow in each area photographed was expressed as the percentage of available marrow space occupied by cellular marrow. The average of the 4 determinations for each animal gave the bone marrow index, which is defined⁷ as the average percentage of available marrow space occupied by hematopoietic marrow. To obtain an index for each cell type, the total bone marrow index was multiplied by the percentage of individual cell types determined by differential counts of bone marrow smears prepared from the same animal. The basic concept of reporting bone marrow findings in this way is comparable to recording absolute counts of individual cell types in the peripheral blood rather than percentage figures of the total leukocyte count. Of necessity the standard of reference in the bone marrow is the available marrow space, while peripheral counts can be expressed in cells per cu. mm. The indices give a clear picture of the depletion of the marrow and the rate of subsequent regeneration of the various cell types. Bone marrow indices rather than differential counts are therefore used throughout this paper, with one exception. Subgroups of the myeloid series are reported as percentages of the total myeloid cells, as shifts to the left or right are meaningful with reference to the myeloid series only and not with reference to the available marrow space.

The classification of the granulocyte series in the bone marrow of small rodents presents certain difficulties, which have been discussed in an earlier paper by Endicott and Ott.⁷ In the mouse as in the rat, maturation of the nuclear chromatin and of the cytoplasm of the granulocytes may proceed independently.

Young nuclei of round or oval shape with finely divided chromatin are frequently present in cells with old neutrophilic cytoplasm, while other cells show young basophilic cytoplasm and old ring form nuclei with coarsely distributed chromatin. This independent maturation of nucleus and cytoplasm makes any attempt to arrange the granulocytic series into definite promyelocyte, myelocyte and metamyelocyte stages highly artificial and subject to extreme variation from differences of interpretation. However, the very young and the definitely mature granulocytes are easily identifiable. For this reason the following classification was adopted:

a Young forms Relatively large cells with blue cytoplasm, with or without azurophilic granules, with round or early ring form nuclei, and finely divided nuclear chromatin.

b Old forms Cells with pale blue or neutrophilic cytoplasm, with ring form nuclei showing early indentation or fully developed segmentation and coarsely distributed chromatin.

c Intermediate forms All other cells of the granulocyte series, i.e., cells showing partial maturation of cytoplasm and nuclear chromatin in various combinations.

The above classification cannot be correlated exactly with the standard division of granulocytes into promyelocyte, myelocyte and metamyelocyte stages. It is felt that this disadvantage is outweighed by the ease with which differential counts on the same specimen can be reproduced by different observers. Any discrepancies can usually be traced to failure to take counts from at least 3 representative areas. The larger cells of the early granulocyte series and the small normoblasts tend to accumulate at opposite ends of the smears. For this reason, the beginning, middle and end portions of each smear were counted, going from the middle to one edge of the slide in each of these areas. Using this method, total cell counts usually comprise 800 to 1500 cells.

The average weights of the animals, the organ weights, peripheral blood counts and myelograms of the first series of mice killed in groups of six at the above stated intervals after irradiation are recorded in tables 1-4. Duplicate experiments were performed on a second series of animals of the same strain, sex and age and on a third series of mice of the same strain and sex, but 5 to 6 months old. The peripheral blood counts and myelograms for the latter two groups showed no significant deviation from the data of the first series recorded in our tables. Histologic findings were identical in all experiments. In a further small series of animals sections of lymph nodes, thymus, spleen, and bone marrow were examined 1, 2, 3, 7 and 18 hours after irradiation, but no blood counts or myelograms were taken.

Four groups of six control mice of the same strain and sex were examined at various intervals in the course of the experiment. The age of the animals was 2 months in 3 of these groups, and 5 months in the 4th group. In contrast to the narrow range of WBC counts in irradiated animals, individual WBC counts in the 24 control animals ranged from 5800 to 25,000. However, leukocyte counts of control animals in any one group of six tended to be on either the high or the low side, and fell within a relatively narrower range.

Control	12.0 ± 3.4	32.9 ± 7.0	55.1 ± 8.5

For estimates of the degree of leukopenia in irradiated animals it is desirable to know the lower limit of the normal leukocyte count rather than the average count. For this reason the means and the standard deviations of the leukocyte count of each of the four groups of control mice were computed. The group

showing the lowest average leukocyte count is recorded as control group in our tables. The standard deviation of this group indicates that $\frac{2}{3}$ of any group of animals with low normal counts may be expected to have lymphocyte counts of 5000 or more. Myelograms of all four control groups did not differ significantly.

TABLE 4—*Peripheral Blood Counts (WBC per cu mm) in Mice Given Whole Body X-radiation of 400 r (Means and Standard Deviations)*

ORGAN WEIGHTS

The weight of the lymph nodes, spleen and thymus was considerably below normal 1, 2 and 4 days after irradiation. The weight of the thymus and the lymph nodes was again within normal limits 7 days after irradiation. The weight of the spleen was considerably increased over previous low values at 10 days, but did not reach normal until the 14th day after irradiation. The weights of all organs examined 21 and 28 days after irradiation did not differ significantly from those of the controls. The size of the lymphoid tissues observed at autopsies corresponded to the variations in weight recorded in table 1.

HISTOLOGIC FINDINGS

Lymph nodes (controls) Forty superficial cervical lymph nodes from 12 control mice, 2 months old, were studied as a basis for comparison with those of x-rayed mice. The capsule of the nodes is thin. As a rule there are no trabeculae. Medullary cords form the central core of the nodes and project in narrow bands toward the surface, dividing the cortical lymphoid tissue into ovoid masses of varying size. Follicles with more or less well developed secondary centers are present in greatly varying numbers. They are always located near the surface of the node, either embedded in a mass of cortical lymphoid tissue, from which they are demarcated by a rim of closely packed lymphocytes, or flanked by medullary cords.

The term cortical lymphoid tissue, as used here, is identical with the "substance corticale" of Jolly and the "Rindenknotten" of Hellman. In a loose network of reticulum cells and fibrils it contains free cells, mostly small lymphocytes, whose nuclei are frequently angular, indented or lobated, occasionally to an extent simulating a mitosis. Mitotic figures are rare in the cortical lymphoid tissue.

The follicles consist of medium sized and large lymphocytes, a few of which are seen in mitosis, and of a small number of large phagocytic cells. These contain

tingible bodies of Fleming, frequently clearly identifiable as disintegrating lymphocytes. A zone of closely packed, small lymphocytes surrounds the paler center. The term secondary center is used by us for this paler central zone, while the term secondary nodules is reserved for the entire follicle consisting of the paler center and the peripheral rim of closely packed lymphocytes. Reticulum is very scanty in the secondary centers.

The medullary cords consist of a central vessel surrounded by a concentric collar of large cells. These cells have a broad, slightly irregular rim of deeply basophilic cytoplasm and often somewhat eccentric nuclei of the lymphocytic type. They have been described as polyblasts and as plasmoidocytes.^{11,18} Occasionally cells in mitosis are present. Plasma cells in varying numbers can usually be found in the medullary cords. The intermediary and medullary sinuses are sharply outlined by the marginal reticulum fibrils limiting the medullary cords.

The peripheral and intermediary sinuses are usually empty. A few medullary sinuses near the hilum frequently contain large numbers of polygonal or round cells, with an ample amount of oxyphilic cytoplasm. These probably represent desquamated lining cells of the sinuses. Mast cells in varying numbers are often present in the intermediary and medullary sinusoids. No appreciable amount of connective tissue is present in the hilum of the nodes.

Lymph nodes of irradiated animals. Sections taken 2 and 3 hours after irradiation showed widespread disintegration of lymphocytes. Large amounts of nuclear debris were present in macrophages in the secondary centers and occasionally in the cortical lymphoid tissue. At 7 hours cellular debris was also present in the medullary cords. At 18 hours hardly any lymphocytes remained in the secondary centers, which contained only swollen, poorly staining cells and large macrophages filled with cellular debris. The peripheral rim of closely packed lymphocytes, normally surrounding the secondary centers, was still well preserved in some of the follicles (fig. 1a). Other follicles had lost this collar of small lymphocytes and the former secondary centers, containing debris-laden macrophages, bordered directly on the peripheral sinuses (fig. 1b). Small accumulation of nuclear debris were still present in medullary cords and in the cortical lymphoid tissues. Presumably this debris was to a large extent ingested in macrophages, but the phagocytosing cells did not stand out clearly except in the secondary centers. A few granulocytes were occasionally present in the sinuses.

After 24 hours nuclear debris was seen only in macrophages in the remnants of the secondary centers. All follicles had now lost their peripheral rim of small lymphocytes. The medullary cords were partly collapsed and their cells often showed pyknotic nuclei. The medullary sinuses were correspondingly widened and the reticulum condensed (fig. 1c). Granulocytes were occasionally present in some of the sinuses.

The macrophages seen in the secondary centers at 7, 18 and 24 hours contained, in addition to nuclear debris, numerous small globules of oxyphilic cytoplasmic material, which stains vividly with periodic acid-leukofuchsin stain.¹⁹ These globules were slightly acid-fast and slightly sudanophilic. Similar macrophages were sometimes also seen in the cortical lymphoid tissue and medullary cords. A

d Spleen, 48 hours 6X Hemosiderin (black) in red pulp Ferrocyanide-hydrochloric acid-fuchsin

At 4 days a narrow rim of large cells resembling lymphoblasts was visible beneath the capsule (fig 3b)

At 7 days a well developed cortical zone was present, but the medulla still contained fewer lymphocytes than normal. From the 14th day on, the appearance and relative size of both cortex and medulla were within normal limits.

Spleen. At 2, 3, 7 and 18 hours nuclear debris was present in large amounts in the Malpighian follicles and to lesser extent in the red pulp. Debris-laden macrophages were clearly seen in some of the follicles (fig. 3c). The small, but fairly numerous centers of erythropoiesis normally present in the mouse spleen, were decreased in size and numbers. Large amounts of brownish, iron-containing pigment appeared in the red pulp. The megakaryocytes were reduced in number and frequently showed pyknotic nuclei. At 24 hours the spleen was greatly reduced in weight. Nuclear debris was seen only in rare macrophages in the follicles which were somewhat reduced in size. Nuclear debris had completely disappeared at 48 hours.

FIG. 4. SPLEEN, 10 DAYS AFTER IRRADIATION. 7X. FOCAL AREA OF HEMOPOIESIS.
HEMATOXYLIN-EOSIN.

Erythropoietic centers were no longer recognizable. Iron-containing pigment was diffusely distributed through the red pulp, partly phagocytosed in the cells of the condensed reticulum, which often contained numerous red blood cells and few lymphocytes. In Giemsa stained sections the follicles stood out sharply against the uniformly pink-staining red pulp. In sections stained for iron the red pulp took a rather intense blue color, while the follicles took the color of the counter stain only (fig. 3d). Megakaryocytes were markedly reduced in number. The appearance of the spleen remained unchanged at 4 and 7 days, except for an occasional mitosis in the follicles. A marked increase in the size of the spleen occurred between the 7th and 10th day, partly due to increase in the size of the follicles, partly due to formation of subcapsular areas of hemopoiesis (fig. 4). These circumscribed foci of hemopoiesis were frequently visible grossly as light-red or whitish subcapsular

nodules, projecting slightly above the surrounding surface of the spleen. In sections these foci were seen to consist chiefly of round cells with a small rim of cytoplasm with large nuclei and well defined nucleoli (fig. 5). Occasional mitoses were seen. In smears, the majority of these cells were identified as pronormoblasts, among which were a small number of myeloblasts. By the 14th day the spleen had enlarged further and its weight, as well as the size of the Malpighian follicles, was within normal limits. Hemopoiesis was in progress throughout the red pulp. Numerous normoblasts and occasional granulocytes were now intermingled with stem cells. The amount of pigment, already reduced at 10 days, now rarely exceeded that of controls. Megakaryocytes were again present in normal numbers. At 3 and 4 weeks the spleen showed essentially the same appearance as at 2 weeks. Myelopoiesis was somewhat more extensive, but erythropoiesis continued to dominate the picture.

FIG. 5. SPLEEN, 10 DAYS AFTER IRRADIATION. 500X. STEM CELLS IN FOCAL AREA OF HEMATOPOIESIS. EDGE OF MALPIGHIAN FOLLICLE IN LOWER LEFT CORNER.

The accumulation of hemosiderin, noted in the spleen after irradiation, was not found in any other organ examined. Hemosiderin in the spleen was most abundant from the 1st to the 7th day. The period of greatest accumulation of hemosiderin thus coincided with the time of greatest reduction in the size of the spleen. Some of the apparent increase in the amount of pigment may therefore have been due to collapse of the splenic stroma with resulting condensation of pigment.

From the histologic appearance alone it was impossible to decide whether this hemosiderosis developed within 24 hours and remained constant over a period of a week, or whether hemosiderin continued to accumulate during the first week. The hemosiderin present at 24 hours was so abundant that any further increase could hardly have changed the histologic picture.

Bone marrow. The diminution and subsequent increase of the total cellular bone marrow are recorded in table 2. Sections showed an increase in the size of blood filled vascular spaces concomitant with the loss of cellular marrow following irra-

diation. A very small amount of cellular debris and slight phagocytosis were noted from 1 to 24 hours after irradiation. Our paraffin embedded sections were generally unsuitable for the study of finer cellular details. The bone marrow changes, as studied by means of quantitative myelograms, are reported with the hematologic findings.

Summary of the histologic findings. Within 24 hours after irradiation, there was extensive destruction of the cells of the secondary centers and medullary cords of the lymph nodes, almost complete destruction of the thymic cortex, diminution of the lymphocyte content of the thymic medulla and marked decrease in size of Malpighian follicles. The weight of the lymphoid tissues was markedly decreased. Regeneration of lymphocytes was first noted at 4 days after irradiation. The lymphoid tissues regained normal weight at 7-14 days. As judged from the histologic appearance, lymphopoiesis was frequently in excess of normal from 14 days on through the rest of the period of observation.

The spleen showed marked hemosiderosis from the first to the 7th day. Due to the marked collapse of splenic stroma during this time, part of this hemosiderosis was probably more apparent than real. No hemosiderosis was found in other organs examined.

Extramedullary hemopoiesis was marked in the spleen from the 10th day on and comprised both the myeloid and erythroid series. Extramedullary myelopoiesis was also prominent in the lymph nodes at 3 and 4 weeks.

HEMATOLOGIC FINDINGS

Cellularity of the bone marrow decreased during the first 4 days after irradiation. The first evidence of recovery was noted at 7 days. The total cellularity was still below normal at 2 weeks. Over 90 per cent of the available marrow space was occupied by active marrow at 3 and 4 weeks. The different cell types showed marked differences in rate of diminution and regeneration.

The first regeneration of nucleated red cells of the marrow was noted at 7 days. Average indices reached normal at 10 days, but fell again by 14 days and remained below normal throughout the period of observation.

The statistically significant fall in nucleated red cells at 3 weeks and the renewed increase at 4 weeks is in essential agreement with the data of Langendorff and Papperitz,¹⁰ who believe that regeneration of hematopoietic tissues after x-ray injury proceeds in waves. The possibility of excessive myelopoiesis suppressing erythropoiesis appears to fit the data well, especially as the slight decrease in myelopoiesis at 4 weeks is accompanied by a corresponding increase in nucleated red cells.

The reticulocyte count in the peripheral blood dropped from its average normal value of 2.0 per cent to 0.2 per cent within 24 hours after irradiation. It remained at this low level at 2 and 4 days. After 7 days up to 0.8 per cent were found. On the 10th day reticulocyte counts varied from 2.0 per cent to 22.0 per cent. From the 14th day on reticulocyte levels ranged from 2.0 per cent to 5.0 per cent.

The rapid reticulocyte drop within 24 hours after irradiation would indicate a rather short lived reticulocyte stage of the red cell in the mouse.

Total red cell counts, hematocrit and hemoglobin values dropped only slightly during the first 4 days after irradiation. They were markedly reduced between the 7th and 14th day. The lowest average values were observed in one group of six animals examined and killed on the 10th day (RBC 6,600,000 \pm 800,000, Hb 14.0 \pm 2.0, hematocrit 33 \pm 9). At 3 weeks only slight residual anemia was present. At 4 weeks total red cell counts were frequently within normal limits (Control group RBC 9,600,000 \pm 1,300,000, Hb 18.4 \pm 1.8, hematocrit 51.0 \pm 0.5). In most groups examined the 2-week-values were below the one-week-levels but occasionally the reverse was the case.

The myelopoietic marrow diminished more gradually than the red cell precursors. The lowest level was reached at 4 days. Regeneration proceeded quickly and the myelopoietic indices were above normal from the 14th day on. The period of observation is too short to determine whether the slight but significant drop in myelopoiesis at 4 weeks indicates a return to normal values or not.

The peripheral granulocyte counts reflected the marrow changes accurately. As in the marrow the lowest granulocyte level, amounting in some animals to agranulocytosis, was reached at 4 days. There was slight recovery by the 7th day. A marked left shift was present both in the marrow and in the peripheral blood at 10 days.

Marrow lymphocytes, normally representing almost 20 per cent of the active marrow cells, dropped to a low value within 24 hours. Lymphocytes in the marrow remained scarce until the end of the observation period, except for an abrupt, temporary rise around the 10th day. The cells recorded as lymphocytes in our 10-day-data included a varying number of large cells with dark blue cytoplasm and with somewhat finer distribution of nuclear chromatin than that of mature lymphocytes. Some of these cells showed great similarity to myeloblasts, but lacked nucleoli. These cells are probably identical with the lymphoidocyte of Pappenheim. We feel that the morphology of these cells is not sufficiently distinctive to permit them to be differentiated from lymphocytes when they are present in small numbers only. We have therefore recorded them with the lymphocytes.

As to the function of these cells, however, there is reason to believe that they are stem-cells of the granulocytic series. Cells of this type did not appear in the peripheral blood, a fact which supports the contention that they are stem cells. Their appearance in the bone marrow coincided with a marked left shift in the granulocytic series and preceded a rapid increase of myelopoiesis. This suggests that these lymphocyte-like cells are stem-cells of the myeloid series.

DISCUSSION

There is general agreement in the literature, as reviewed by Dunlap,¹¹ that lymphoid, myelopoietic and erythropoietic tissues show increasing resistance to x-radiation in the order named. In contrast, the almost complete disappearance of normoblasts from the bone marrow within 24 hours of irradiation in our experiments points to a considerable sensitivity of red cell precursors to radiation. The bone marrow did not show the striking phagocytosis of cellular debris found in the lymphoid tissues. However, in view of the vascularity of the bone marrow and

the probable intravascular development of erythroblastic cells, cellular debris might be expected to be flushed out rapidly. For this reason, the small amount of cellular debris and phagocytosis in the bone marrow does not exclude the possibility of widespread disintegration of red cell precursors, such as would account for the drop in normoblasts and the rapid accumulation of hemosiderin in the spleen. Evidence of direct damage to, and disintegration of, erythroblasts in the bone marrow following x-ray injury has recently been described by Bloom and Bloom.¹² These authors used x-ray dosages similar to ours, but different techniques for the study of the bone marrow. They concluded that the erythroblasts in mice, rabbits and rats are more susceptible to radiation damage than are myelopoietic cells. The erythroblast of the chicken appeared at least as sensitive to radiation as did the small lymphocytes which are commonly found in nodules in the chicken marrow.

Peripheral blood counts showed an almost immediate drop in lymphocytes, and a more slowly developing granulocytopenia. This is in keeping with the longer life span of granulocytes and the slower diminution of myeloid cells in the bone marrow. Granulocyte levels rose again with myeloid regeneration. Lymphopenia was, however, more prolonged than granulocytopenia. At 2 weeks the lymphocyte count was still only 50 per cent of the lower limit of normal, although the lymphoid tissues had regained their normal weight and lymphopoiesis appeared to be slightly in excess of normal. The lymphopenia in the bone marrow was even more marked and prolonged. This lag between resumption of active lymphopoiesis in the tissues and recovery of normal lymphocyte levels in the peripheral blood has been observed in other species.¹³ The significance of this lag period is obscure. It is conceivable that the slow return of the peripheral lymphocyte count to normal levels is due to the fact that lymphopoiesis exceeds normal only by a slight margin during regeneration. After replacing the daily loss of lymphocytes from the peripheral blood, only a small excess would remain and a considerable time would be required to restore the peripheral lymphocyte count from its low level following irradiation. On the other hand, the lag in recovery of peripheral lymphocyte counts may be due to disturbances of the mechanism regulating the release of lymphocytes from the tissues and their distribution throughout the body. Most likely several factors are in operation following irradiation and the rate of recovery of the peripheral lymphocyte count should not be expected to reflect necessarily the activity of, or the amount of original damage to, the lymphoid tissues.

No evidence of diminution or proliferation of the reticuloendothelial cells was found. The only function of the cells of the RES that can be studied morphologically, their ability to phagocytose, appeared to be intact throughout the period of observation. In the lymph nodes phagocytosis of cellular debris was extensive during the first 24 hours, due to extensive destruction of lymphocytes, and was again marked, in conjunction with active regeneration of lymphocytes, from the 4th day on. In the spleen large amounts of hemosiderin were present in phagocytic cells from the 1st to the 7th day after irradiation. The ability of the RES to phagocytose appeared also intact in experiments (unpublished) in which carbon particles were injected intravenously in mice of the same strain, age and sex, at varying intervals after irradiation with 400 r. In these experiments active phagocytosis of

carbon particles by the reticuloendothelial cells of the liver, spleen and bone marrow was comparable to, or in excess of, that observed in nonirradiated mice

Our basic problem, to estimate the duration of suppression of lymphoid and hematopoietic activity, can receive only a qualified answer. Estimates based on the histologic appearance of the lymphoid tissue suggest that the limit of marked suppression of lymphopoiesis was about 14 days. Peripheral lymphocyte levels were still below normal at that time and this would indicate a longer time interval between irradiation and recovery. Total granulocyte counts reached normal levels at 14 days. Again estimates of the recovery time may vary somewhat, as the number of fully segmented granulocytes reached normal levels somewhat later than the total granulocyte count. The practical problem is simplified by the fact that damage to the myeloid tissues, though probably of slighter degree, is still quite severe during the first 10 days. This would certainly leave too narrow a time margin for any experiments designed to demonstrate the relative function of granulocytes and lymphocytes based upon a supposed selective suppression of one cell type. The lack of any morphologic evidence of damage to the reticuloendothelial system suggests that functional studies concerned with the relative functions of the lymphoid tissues and the RES may be undertaken during the first 2 weeks following irradiation under the experimental conditions used. Such experiments must be interpreted cautiously because of the concomitant damage to the bone marrow and because of the possibility that the RES may have been altered in functional capacities other than its ability to phagocytose.

SUMMARY

Quantitative myelograms, peripheral blood counts and the histologic appearance of lymphoid tissues were studied in albino mice of the CFW strain during a period of 4 weeks following single whole body radiation of medium dosage.

Nucleated red blood cells disappeared almost completely from the marrow within 24 hours after irradiation. Regeneration of the erythroid series commenced around the 7th day. Only mild to moderate anemia developed, presumably due to the longevity of red blood cells.

Suppression of mitotic activity and diminution of the myeloid marrow was marked during the first week after irradiation. Granulocytopenia in the peripheral blood was severe for a very short period only. In contrast, early damage to the lymphoid tissue was more pronounced and lymphopenia was of longer duration than granulocytopenia in spite of early regeneration of the lymphoid tissues. Differences in the relative amount of damage to lymphoid and myeloid tissues and in their rates of regeneration were not of sufficient magnitude to indicate a truly selective damage to the lymphoid tissues under the conditions of our experiments.

No morphologic evidence of damage to the reticuloendothelial system was found. The possible use of irradiated animals for functional studies of the lymphoid apparatus is discussed.

PLATELET ADHESIVENESS

B₃ MURRAY WEINER, M D , KURT ZELTMACHER, M D , CARL REICH, M D ,
AND SHEPARD SHAPIRO, M D

IN 1941, Helen Wright¹ described a method for estimating the adhesive quality of platelets. Confirmation of the original findings by Spooner and Meyer² established the procedure as a means of distinguishing this property of platelets. It is the purpose of the present report to evaluate the usefulness of the method in clinical medicine.

METHOD

Five ml of blood is obtained by clean venipuncture with a dry needle and syringe, and delivered into a small dry bottle containing 8 mg potassium oxalate and 4 mg ammonium oxalate. * The bottle is gently rotated to aid solution of the oxalate. Within 10 minutes a 2 ml sample of this oxalated blood is pipetted into a glass tube with a bulbous dilatation at one end. The tube is then rotated at 7 r p m. Samples for serial platelet counts are withdrawn before rotation is begun, and every 20 minutes for 80 minutes. The platelet counts are made using the standard red cell pipet with Reese-Ecker diluting fluid to which 2 per cent formaldehyde has been added. The diluting fluid is autoclaved after it is prepared, and stored at refrigerator temperature. Each portion is filtered before it is used. The counting chambers are placed on wet filter paper and covered with a petri dish after being loaded. This permits the platelets to settle without drying on the chamber for about a half hour before the count is made. By this technic large clumps of platelets are rarely seen, and microorganisms which may be confused with platelets are kept at a minimum.

The serial platelet counts are calculated in terms of per cent of the initial count, and a curve is plotted with the number of remaining platelets as ordinate and the time in the rotating tube as abscissae. The curve then represents the proportion of platelets which have failed to adhere to the wall of the rotating tube. In normal individuals, platelet counts usually fall to about 30 per cent of the initial count in 80 minutes. Adhesiveness determinations carried out in 22 adults without evidence of disturbed coagulation or phenomena indicative of vascular alteration, yielded counts of from 25 per cent to 40 per cent of the initial count in 80 minutes. In almost every case, the estimations were made in duplicate. The initial counts ranged from 140,000 to 220,000 per cmm. The data obtained in the 22 subjects is summarized in the solid curves of figure 3.

Since platelet counts vary widely when made by different observers, the counts have been made by one person especially practiced in the procedure, who had attained thoroughly consistent manipulative characteristics. We have found the procedure time consuming and inconsistent when the technic was varied only slightly. Prothrombin estimations were made by a method previously described.³ Fibrinogen levels were established by determination of the protein content of plasma before and after the contained fibrinogen was coagulated and removed.

RESULTS

The present report embraces a study of the curves of platelet adhesiveness in 110 instances which include both normal and a large variety of disease states.

From the Third (New York University) Division, Goldwater Memorial Hospital, Welfare Island, N Y 17, N Y, the Lenox Hill Hospital, and the Department of Medicine, New York University College of Medicine.

Aided by a grant from the Blood Transfusion Association of New York.

* Since this paper has been submitted, we have been using 0.2 mg heparin per ml blood in place of the oxalate.

No abnormality in platelet adhesiveness was demonstrated in a large variety of diseases in which disturbed coagulation was not a factor. These include infectious mononucleosis, 2 cases, erythema multiforme, 1 case, pulmonary hemorrhage secondary to bronchiectasis, 1 case, duodenal ulcer, 2 cases, one actively bleeding, rheumatic heart disease, 3 cases, arteriosclerotic heart disease, 4 cases, hypertensive heart disease, 4 cases, diabetes mellitus, 2 cases, rheumatoid arthritis, 2 cases, amyloid disease, 1 case, subarachnoid hemorrhage, 1 case, and multiple sclerosis, 1 case. The detailed data which follow represent instances in which altered adhesiveness of the platelets and/or coagulability were demonstrated.

FIG. 1. PATIENT G. EFFECT OF HYPERPROTHROMBINEMIA INDUCED BY LARGE DOSES OF VITAMIN K.

Solid line indicates Control (diluted, 12.5 per cent, plasma prothrombin Time, 42 sec normal). Broken line indicates third day (12.5 per cent plasma prothrombin time, 35.2 sec). Dotted line indicates fourth day (12.5 per cent plasma prothrombin time, 31.8 sec).

1. Platelet Adhesiveness in Hypercoagulable Blood

The adhesiveness of the platelets was studied in conditions in which the blood was hypercoagulable. It is possible to induce this condition experimentally in some subjects with normal liver function.⁴ It occurs spontaneously in some cases of intravascular thrombosis. It is detectable by a reduction in prothrombin time to a level below the limits of normal (hyperprothrombinemia) and/or thrombocytosis.⁵

(a) Hyperprothrombinemia Induced by Vitamin K⁴

Synthetic vitamin K (Synkayvite) (Tetrasodium 2-methyl-1,4-naphthohydroquinone diphosphoric acid ester) 76 mg daily on four successive days was given to a subject with normal liver function, in order to induce hyperprothrombinemia (fig. 1).

Day of therapy	Prothrombin time of diluted (12.5%) plasma*	Fibrinogen	Initial platelets in 80 minutes
	seconds	mgm/100 ml	%
Control	42 2	410	29
Third	25 2	400	13
Fourth	31 8	450	9
Sixth	42 0		20

* Normal range 37-42 seconds

(b) *Reactive Thrombocytosis and Hyperprothrombinemia in Thrombosis*⁵

Diagnosis	Prothrombin time of diluted (12.5%) plasma*	Platelet count per cmm	Initial platelets in 80 minutes
	seconds		%
Acute venous thrombosis	33	600,000	30
Acute coronary thrombosis	Not made	600,000	24

* Normal range 37-42 seconds

2 *Platelet Adhesiveness in Hypocoagulable Blood*

(a) *Dicumarol-induced Hypoprothrombinemia*^{2 6} (fig 2)

Prothrombin time of whole plasma	Initial platelets in eighty minutes	Diagnosis and remarks
seconds	%	
24 0	53	Pulmonary embolus, on dicumarol therapy
30 0	53	
24 0	55	
15 0	30	Recovered Therapy withdrawn

(b) *Thrombocytopenic Purpura*

A 20 year old white male showed the clinical manifestations of thrombocytopenic purpura. The platelet counts varied between 22,000 and 220,000 and were usually below 80,000 per cmm. The intensity of the clinical symptoms could not be correlated with the degree of thrombocytopenia. The prothrombin time, fibrinogen concentration, clot retraction and clotting time were consistently normal. Four determinations of platelet adhesiveness were made. The initial counts varied between 60,000 and 220,000. In none of these did the count fall below 47 per cent of the initial value after eighty minutes. The average count after eighty minutes was 53 per cent. The average of the four determinations is compared to the normal in figure 3.

(c) *Spontaneous Purpura in Pregnancy*

A 26 year old female para 1 gravida 1, commenced to show diffuse purpuric hemorrhages during the sixth month of pregnancy. Physical examination revealed no other positive findings. Prothrombin time, fibrinogen concentration and clotting

FIG 3 PLATELET ADHESIVENESS IN THE NORMAL AND IN THROMBOCYTOPENIC PURPURA

Curve A represents the average value of 22 normal individuals. Curves B and C represent the average deviation of these normals. Curve D is the average of 4 estimations made in a patient with thrombocytopenic purpura. The initial platelet counts varied between 60,000 and 220,000.

time were normal. The platelet count was 158,000 and the adhesiveness curve yielded a fall to 67 per cent of the initial count in 80 minutes. The purpuric condition subsided spontaneously one month later, and the adhesiveness curve became normal.

minutes	During hemorrhagic phase	After recovery
	per cent of initial count	%
20	84	75
40	85	48
60	80	42
80	67	32

(d) *Prolonged Clotting Time and Hemorrhage*

A male adult with chronic rheumatic valvular disease, exhibited continuous oozing of blood from the gums for three days after a tooth was extracted. The bleeding and prothrombin times were normal, but the clotting time was slightly prolonged to seven and one-half minutes by the rotating tube method² (Upper limit of normal is six and one-half minutes). At that time the platelet count was 140,000 and the adhesiveness curve fell to 30 per cent in 80 minutes. After the hemorrhage ceased, the clotting time became reduced to normal (four and one-half minutes) and the platelet count increased to 370,000 and the adhesiveness curve yielded a reduction to 18 per cent of the initial count in sixty minutes, which is indicative of an increase beyond normal.

FIG. 4. PATIENT R. HEMOPHILIA

Solid line indicates control. Broken line indicates coagulation time reduced by Fraction 1.

(e) *Chronic Myelogenous Leukemia*

A male adult with chronic myelogenous leukemia began to show diffuse purpura concomitantly with marked increase in peripheral myeloblasts. The platelet count was 262,000 but the adhesiveness curve fell only to 82 per cent of the initial count in eighty minutes. The clotting time and prothrombin time were normal. The patient died of exsanguination three days later.

(f) *Hemophilia: Effect of Antihemophilic Fraction one**⁸

An 18 year old Negro male of unknown parentage showed the coagulation defects characteristic of hemophilia since early childhood. The bleeding time, prothrombin time, and fibrinogen content of the plasma were normal. The clotting time, when the present study was made, was sixty-nine minutes by the rotating tube method (Normal = four to six and one-half minutes). The platelet adhesive-

* Fraction 1 was prepared from blood collected by the American Red Cross under a contract the Office of Scientific Research and Development and Harvard University. It was supplied the courtesy of Dr. Louis K. Diamond.

ness curve fell to 38 per cent in eighty minutes (upper limit of normal) Anti-hemophiliac fraction 1 was administered intravenously. The coagulation time became reduced to 16 minutes and the adhesiveness of the platelets increased to 23 per cent in eighty minutes (fig. 4).

A 40 year old white male with hemophilia the diagnosis was established in early childhood. The coagulation time ranged between 37 and 47 minutes by the rotating tube method (normal = four to six and one-half minutes). On numerous occasions, platelet adhesiveness was determined and averaged 32.5 per cent of the initial count in eighty minutes. He was given fraction 1 intravenously, and the clotting time was reduced to between four and ten minutes at various times. Platelet adhesiveness estimated when clotting time was reduced to normal, yielded an average of 24 per cent (two estimations) in eighty minutes.

SUMMARY OF FINDINGS

In the presence of hypercoagulable blood occurring spontaneously in association with thrombosis or artificially induced by large doses of vitamin K, the adhesiveness of the platelets was generally increased. In the spontaneously occurring cases, the change was not constant, instances of normal adhesiveness having been observed even in the presence of marked thrombocytosis. Hypocoagulable blood, whether occurring as part of a blood dyscrasia, or induced by dicumarol, was accompanied more consistently by decreased adhesiveness of the platelets. In hemophilia, the clotting time and the adhesiveness simultaneously were reduced following restoration of coagulability to normal by Fraction 1.

In several cases exhibiting hemorrhagic phenomena, decreased stickiness of the platelets was the only defect found in the coagulation mechanism.

DISCUSSION

Adhesiveness of platelets appears to be dependent upon at least two factors: the intrinsic properties of the thrombocyte surface, and the character of the medium in which the platelets are suspended. It is believed⁹ that fibrinogen is converted into fibrin on the surface of the platelets, and that adhesiveness is the result of this change. It would follow then, that inhibition of the clotting mechanism should impair the adhesive capacity of the thrombocytes and conversely, that augmented coagulability should accelerate adhesiveness. The findings confirm the first hypothesis but support the latter with less constancy in hypercoagulability accompanying thrombosis. Hypocoagulable blood may be induced by deficiency of any component factor of the clotting mechanism. Thrombosis, on the other hand, appears to be the result of a combination of events of which hypercoagulability of the blood may, or may not, be one. In addition, in thrombotic disorders, anticoagulants may be elaborated into the blood stream, presumably as a protective mechanism, so that, when examined *in vitro*, the behavior of the thrombocytes may vary according to the particular type of response operating at the time the specimen is obtained. Nevertheless it seems logical to assume that in a given case, the detection of increased adhesiveness of the thrombocytes warrants pursuit of the possibility of thrombosis being present or imminent. In earlier studies² we have found evidence of increased prothrombin activity in the presence of intravascular

thrombosis, and have suggested it as a diagnostic aid, both in the detection of thrombosis (especially in inaccessible locations) as well as in the selection of probable candidates for the complications. The practical application of the detection of hypercoagulability of the blood, particularly in postoperative cases, and following parturition, is obvious. Studies of this kind in inadequately understood disease states accompanied by thrombosis such as thrombocytopenia with platelet thrombus formation¹⁰ might shed some light on the mechanism underlying the disorder.

The correlation noted in some of our cases, between the state of coagulability of the blood and adhesiveness of the platelets, seems to support the fibrin theory of stickiness of thrombocytes. A few observations seem to require additional explanations. Microstaining studies have not revealed fibrin on platelet surfaces.¹¹ In the presence of the markedly increased clotting time in hemophilia, the detectable differences in adhesiveness as compared with the normal have been relatively slight, while in dicumarol-induced prothrombinopenia of moderate severity, much greater interference in platelet adhesiveness is the rule. In the cases in which fibrinogen determinations were made, the changes in platelet adhesiveness were found to occur independently of the concentration of this protein in the plasma.

The deficiency in adhesiveness of the platelets noted in hemophilia is of particular interest. Since the blood is hypocoagulable, it is not possible to determine from the present study whether or not the platelets are functionally defective in hemophilia. The stickiness of the thrombocytes is promptly increased when the coagulation defect is corrected by Fraction 1. It is possible that the improved adhesiveness is an expression of the more normal coagulability of the blood.¹² In thrombocytopenic purpura, we have found Fraction 1 to be without effect.¹³ This phase of the study is being extended in this laboratory.

The two cases of bleeding described above (cases c and e) in which deficient adhesiveness of platelets was the only detectable defect in the coagulation mechanism, suggest that a knowledge of the state of the stickiness of thrombocytes may be of assistance in explaining instances of hemorrhagic tendencies which do not fall in categorized syndromes.

SUMMARY AND CONCLUSIONS

The method described by Helen Wright for estimation of the adhesiveness of platelets has been found to be reproducible. Adhesiveness of platelets is reduced in the presence of hypocoagulable blood. It may or may not be enhanced when the blood is hypercoagulable. In hemophilia, the adhesiveness of platelets has been found to become increased beyond the premedication level when the coagulation defect is corrected by Fraction 1 derived from human plasma. Two cases exhibiting bleeding are described in which deficient adhesiveness of the thrombocytes was the only demonstrable defect noted in the coagulation mechanism.

CHRONIC LEG ULCER IN DISEASES OF THE BLOOD

By BENJAMIN R. GENDEL, M D

CHRONIC LEG ULCERS have been described as a complication of several diseases of the blood and are best known in association with sickle cell anemia. Diggs and Ching¹ reported that chronic ulcers or scars of old ulcers were present in 75 per cent of adults with this disease. However, it is less commonly appreciated that other diseases of the blood may present the complication of chronic leg ulcer. In 1925, Gansslen² mentioned a 19 year old patient with congenital (hereditary) hemolytic anemia who, over a period of nine months, had recurrent leg ulcers which resisted therapy, but healed eight days after splenectomy. Since that time over twenty patients with hemolytic anemia have been reported with chronic leg ulcers. The exact incidence of this complication is difficult to determine, but Vaughan³ described the occurrence of leg ulcers in three patients of a series of 18 with congenital hemolytic anemia. Taylor⁴ reported one patient with leg ulcer among 43 patients with hemolytic anemia. The combined incidence for the complication of leg ulcer in these two series is 6.5 per cent. Following the report of Taylor which summarized the previous literature, two cases were reported by Leger and Orr⁵ and another by McGovern.⁶ The ulcer complicating hemolytic anemia occurs in younger people and is located on the lower one-third of the legs. Ulcers were usually several centimeters in diameter and were surrounded by an area of pigmented skin. In half the cases, the ulcers were bilateral. In the majority of instances healing occurred rapidly after splenectomy, although the lesions proved refractory to previous therapeutic efforts.

Several French authors⁷⁻⁸ have noted the association of chronic leg ulcer with splenomegaly. The diagnosis in their cases is not clear, but they seem to represent patients with Banti's syndrome of congestive splenomegaly because leukopenia and recurrent hematemesis were present. Witts⁹ reported two patients with idiopathic thrombocytopenic purpura complicated by indolent leg ulcers. His first patient was a 21 year old female with thrombocytopenic purpura of nine years duration. Six years earlier an ulcer appeared on the left leg which did not heal for two years. Subsequently an ulcer appeared on the right leg, but healed in less time. Both remained healed thereafter. The second patient, a 26 year old man with a lifelong history of excessive bruising and bleeding, had chronic leg ulcer for eight or ten years. The weight of the spleen removed at operation was 122 Gm. In this case there was no improvement of either the general condition or the leg ulcer after splenectomy. Witt also stated that leg ulcers occurred in Gaucher's disease.

The unique occurrence of leg ulcer in pernicious anemia was reported by Lasch.¹⁰

From the Medical Service, Veterans Administration Medical Teaching Group, Kennedy Hospital, Memphis, Tennessee.

Published with the permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the author.

His patient had bilateral, symmetrical, deep ulcers above the ankles almost as large as the palm of one's hand. Varicose veins were not present. The patient had the typical picture of pernicious anemia with slight jaundice, histamine fast achylia, glossitis, macrocytic anemia with high color index, and megaloblastic bone marrow. The spleen was slightly enlarged. Following treatment with liver extract, healing began coincident with the reticulocyte peak on the fifth day, and the ulcer healed completely. A patient with chronic hemolytic polycythemia was described by Rau and co-workers.¹¹ Their patient, a 37 year old female with a five year history of fatigue, had ulcers of the lower legs. Blood studies revealed a polycythemia, spherocytosis and increased fragility of the red cells.

It is apparent from the preceding review of the literature that leg ulceration may occur in the course of a number of diseases associated with hemolytic anemia or splenomegaly. It is the purpose of this report to describe two patients with disorders of the blood aside from sickle cell anemia, who had complicating leg ulcer, and to discuss some of the possible mechanisms for this interesting association. In one of these patients the leg ulcer was the first symptom of the disease.

CASE REPORTS

Case 1 The patient, a 52 year old white man, entered the hospital because of recurrent right upper quadrant pain and jaundice, of seven years duration. These attacks were intermittent and accompanied by dark urine, light stools, fever and vomiting. In May and October, 1946, the patient had similar attacks of obstructive jaundice. Splenomegaly was noted several years before admission. The patient also complained of a chronic leg ulcer just above the left ankle of about twenty-seven years duration. This was previously considered to be a varicose ulcer despite the absence of varicose veins. A skin graft had been done in another hospital in November, 1946, prior to his admission to this hospital, and healing had progressed satisfactorily, although the healing ulcer exuded a serous fluid on dependency of the leg.

The past history revealed that since 1932 the patient had recurrent pain in both knees, occasionally accompanied by slight swelling. An uneventful appendectomy had been performed in 1932. In October, 1945, the patient was hospitalized at another hospital for an acute nephritis characterized by edema, hypertension, albuminuria, and hematuria, all of which gradually cleared up in several months.

The family history revealed no instance of a similar disease. A complete examination of all members of the family was not possible, but two siblings who were examined showed no evidence of hemolytic anemia.

Physical examination revealed an acutely ill, febrile, anemic man with moderate icterus. The blood pressure was 140/80. Heart and lungs were normal. No significant lymph node enlargement was present. The liver was not palpable but there was tenderness over the gallbladder region. Spleen was readily palpable three fingerbreadths below the left costal margin. There was a well healed McBurney scar. An oval ulcer covered by a recent skin graft was noted just above the external malleolus of the left leg (fig. 1). It measured 2.6 cm. in its longest diameter. The remainder of the examination was not significant.

The admission blood count revealed a red cell count of 2,200,000, hemoglobin, 11.5 Gm., white cells, 9,500, 73 per cent polys, 24 per cent lymphocytes, 1 per cent monocytes, and 2 per cent eosinophils. Reticulocytes 8.4 per cent. Platelets normal. The subsequent blood counts are summarized in table 1. The serum bilirubin on admission was 1.3 mgm. Kahn was negative. Repeated urine examinations revealed a low, fixed specific gravity but were negative for albumin and sugar and no abnormal elements were found in the sediment. Repeated uric acid clearance tests varied between 37 per cent and 59 per cent of normal. Examination of a wet preparation of the peripheral blood revealed definite spherocytes (fig. 2). Increased fragility of the red cells in hypotonic saline was noted. Cephalin flocculation, 4 plus in 48 hours. Alkaline phosphatase, 2.6 King-Armstrong units. Prothrombin time, 88 per cent of normal. X-ray examination of the chest and both knees revealed no significant pathology.

After admission, fever continued for the first five days of hospitalization. Tests of the blood for hemo-

FIG 2 CASE 1 LEG ULCER AFTER SKIN GRAFTING

lysins and agglutinins, using both saline and albumin as diluents, revealed no evidence of abnormal agglutinins or hemolysins. A splenectomy was performed on Feb 3, 1947, and a large spleen weighing 1,120 Gm was removed. Three small pieces of tissue considered to be accessory spleens were also removed. On histologic examination the latter were found to be hyperplastic lymph nodes. Following splenectomy, the patient's general condition improved remarkably and the blood count returned to normal. Spherocytes persisted, although in lesser numbers than prior to splenectomy. The ulcer healed completely and has remained well-healed ever since. On May 6, 1947, a cholecystectomy was performed. The gallbladder revealed evidences of chronic cholecystitis and contained several gallstones. A hemorrhoidectomy was performed on July 29, 1947, because of severe symptomatic hemorrhoids. The blood picture has been normal since splenectomy except for a slight persistent spherocytosis, slight leukocytosis and thrombocytosis.

*Case 2** A 60 year old white man gave a history of illness since the autumn of 1943 when he was admitted to a hospital in coma with slight neck rigidity and paresis of the right external rectus muscle. There was a bloody ooze from the gums. The spleen was found to be enlarged. Spinal fluid examination revealed a xanthochromic fluid under increased pressure. Blood studies revealed a pancytopenia. A diagnosis was made of subarachnoid hemorrhage due to an underlying blood dyscrasia of unknown type. Treatment consisted of general supportive therapy including blood transfusions, as a result of which the

patient gradually regained consciousness and the bleeding from the gums ceased. Further workup did not elucidate the nature of the dyscrasia and the patient returned to his home several hundred miles away. Although he was instructed to return for study on completion of his convalescence at home, he was not observed again until Dec 1946 when he consulted a urologist because of bloody urine beginning in Nov 1946 and persisting for four to six weeks. Studies revealed no local cause for the bleeding. A pancytopenia was again noted.

The past history revealed that seven years previously the patient had a tooth extracted and following this there was severe bleeding which necessitated blood transfusion.

The patient's father was reported to have had hemorrhage from the lung presumably due to an infection alleged not to be tuberculosis. A sister had an episode of severe bleeding following extraction of teeth.

The physical examination revealed a markedly obese, elderly, white male. Blood pressure 120/80. Heart and lungs were normal to physical examination. No lymph node enlargement was found. The abdomen was extremely difficult to palpate due to the extreme obesity but the spleen could be felt three fingers below the costal margin. The liver appeared to be enlarged two fingers below the costal margin to percussion. There was a superficial ulcer, about 4 x 6 cm, on the anterior surface of the right leg just above the malleoli. No varicosities were noted.

* The author thanks Dr. Lytle Motley of Memphis, Tennessee, for the opportunity to see this patient and for his permission to report this case.

The blood counts are summarized in table 2. A sternal puncture revealed a nonspecific hyperplasia of the marrow.

The patient was treated with repeated transfusions and showed a slight improvement. He returned home again only to return on March 14, 1947, in a comatose condition. A history of head injury two weeks prior to admission was obtained, followed in ten days by drowsiness, progressing to coma two days before admission. Lumbar puncture revealed a bloody fluid which became clear toward the end of the tap. The patient was treated with nasal oxygen, penicillin and other supportive measures. His temperature rose progressively to 106.6 F on the third hospital day when he expired on March 16, 1947.

An autopsy was performed by Dr. A. Golden, Baptist Memorial Hospital, Memphis, Tennessee, on the same day. The salient features included the presence of the previously noted leg ulcer on the lower right leg measuring approximately 10 cm in length and 4 cm in width. No evidence of intracranial hemorrhage was noted. Numerous pin-point hemorrhages were noted in the intestinal tract and the stomach and intestines were filled with a hemorrhagic fluid. Esophageal varices were noted. The liver (1220 Gm) revealed typical hobnail cirrhosis (Laennec's) and the spleen (800 Gm) showed congestive changes. The final anatomical diagnosis was: Cirrhosis of liver with portal obstruction, splenomegaly, portal hypertensive type, esophageal varices, and hyperplasia of the bone marrow.

DISCUSSION

The first patient presented a typical hemolytic anemia, the earliest symptom of which was the leg ulcer. This proved resistant to treatment over a period of twenty-seven years and finally healed after skin-grafting and splenectomy. Based on previous reports it is possible that splenectomy alone would have been equally efficacious. It is interesting that the fundamental condition was not appreciated and the diagnosis during this time was varicose ulcer, despite the absence of varicose veins. It was impossible to determine definitely whether or not the patient had an hereditary type of hemolytic anemia, because of inability to examine all of the other members of the family, but the persistence of spherocytes after splenectomy suggested the hereditary variety. The second patient presented a difficult problem in diagnosis. At different times a variety of diagnoses were considered but the autopsy revealed cirrhosis of the liver and congestive splenomegaly (Banti's syndrome). The pancytopenia could then be explained by assuming a secondary hypersplenism which developed as a result of the congestive splenomegaly. The patient presented the unusual complication of leg ulcer in association with Banti's syndrome. Similar cases were reported previously by Lombard and Nanta⁷ and by Gregoire and Weill.⁸

The pathology of the ulcerated lesions of the legs has not been characteristic. Essentially, the ulcers revealed a nonspecific infiltration with inflammatory cells, sometimes associated with fibrosis and hemorrhage.^{3, 6, 7} The main value of biopsy would be to rule out other specific leg ulcers such as those due to syphilis or tuberculosis. Biopsies were not undertaken in either of these patients.

The pathogenesis of the leg ulcers accompanying these varied disorders of the blood has not been satisfactorily explained. In the case of sickle cell anemia, it is supposed that the general tendency to vascular thromboses might result in local thrombosis of the skin of the legs and the development of leg ulcer. However, this explanation would not satisfactorily account for the ulcers occurring in the other diseases, in which the tendency to thrombosis has not been noted. Hemolysis occurs in most of these diseases but is not characteristic of either thrombocytopenic purpura or Banti's syndrome. The common denominator would seem to be related

to the spleen. All the diseases in which leg ulcers have been noted, have been accompanied by splenomegaly, with the exception of thrombocytopenic purpura and some patients with sickle cell anemia in whom the spleen may be atrophic. In the former, evidence has been presented for a splenic inhibition of the bone marrow (hypersplenism) to account for the deficiency of platelets.¹² Sickle cell anemia is a hemolytic anemia, and on this basis it can be assumed that there may be some excessive splenic activity accompanying the increased activity of the spleen due to sequestration of the abnormal red cells.

The rapid healing of the ulcer frequently noted following splenectomy suggests a causal relationship between the two, rather than a coincidental occurrence. It is noteworthy that prior to splenectomy many forms of treatment including bed rest have failed to produce healing. Consequently it is suggested that the leg ulcers are another manifestation of a remote effect of the spleen, perhaps a form of hypersplenism mediated in a manner not yet known.

SUMMARY

The literature pertaining to the association of chronic leg ulcer with diseases of the blood other than sickle cell anemia has been reviewed.

Two patients with this association have been presented. One patient had a hemolytic anemia and the other a pancytopenia (secondary hypersplenism) in association with congestive splenomegaly due to cirrhosis of the liver.

It is suggested that the association of leg ulcer with these various diseases of the blood is related in an unknown manner to either splenomegaly or hyperfunction of the spleen (hypersplenism).

A QUANTITATIVE METHOD FOR THE DETERMINATION AND CHARTING OF THE ERYTHROCYTE HYPOTONIC FRAGILITY

By JOHN SUESS, M D , DAVIDE LIMENTANI, M D , WILLIAM DAMESHEK, M D ,
AND MIRIAM J DOLLOFF, A B

THE DETERMINATION of the degree of hemolysis of the red blood cells in hypotonic salt solutions (hypotonic fragility'') has continued to be of considerable interest since Duncan Johann,¹ in 1867, and Malassez,^{2, 3, 4} in 1873, instituted the method of using salt solutions to detect the varying resistance of red cells to hemolysis. Since then, many new technics have been described and much controversial data regarding hypotonic fragility and its interpretation have been amassed. It is only in recent years that full recognition of the importance of this test as a measurement of red cell thickness has been realized.

It is the purpose of this paper to present a new technic for the measurement of hypotonic fragility, based first on the photoelectric determination of the degree of hemolysis and second, upon calculation of the differences in the degree of hemolysis occurring in successive dilutions of hypotonic salt solution. The graphic depiction of these differences, or hemolytic increments, has proved of great value in assessing the red cell population according to its thickness variation, (thickness in relation to diameter), thus indirectly allowing evaluation of the probable type of hemolytic process present.

I REVIEW OF LITERATURE

So many methods for determining the hypotonic fragility have been described that a thorough review of the literature is extremely difficult. In 1867, Duncan Johann¹ reported an increased fragility in salt solutions of the red blood cells of patients with chlorosis. He did not elaborate on his observations and apparently made no attempts to standardize his method.

Malassez,^{2, 3, 4} while attempting to devise a practical method for the counting of red blood cells, observed that cells from different individuals become hemolyzed at different time intervals in the diluting fluid used (a mixture of gum arabic with equal parts of solutions of sodium sulfate and sodium chloride). Malassez then described a quantitative method for the determination of red cell hemolysis consisting of the use of the 'Potain mixer,' (the original red blood cell counting pipet) and in the performance of red cell counts at different time intervals, thus determining the number of residual nonhemolyzed red cells. The time element was of paramount importance. Urcelay,⁵ Malassez's pupil, used a sodium sulfate solution with a specific gravity of 1.010. He established a curve based on the number of nonhemolyzed erythrocytes at different time intervals and concluded that in

From the Ziskind Laboratories (Hematology Section) of the J. H. Pratt Diagnostic Hospital and the Department of Medicine, Tufts College Medical School. Aided by grants from the U. S. Public Health Service. Presented in part at the Red Blood Cell Destruction Conference, St. Louis, Feb. 2, 1948.

normal blood two groups of red cells were present a smaller one of easily hemolyzed red cells and a larger one of cells which were more resistant to hemolysis

Chanel⁶ used three different dilutions of sodium sulfate in water, substituting the factor of dilution for the time factor and performing red blood cell counts to determine the number of nonhemolyzed red blood cells Simmel⁷ and Whitby and Hynes⁸ improved upon his technic Maragliano⁹ (1885 et seq) studied the resistance of erythrocytes to the action of heat, compression, exsiccation and human serum

Hamburger,^{10 11} (1887 et seq) originated the most widely used method, which was modified a number of times by himself and later by others He used test tubes containing solutions of sodium chloride which varied in strength from 0.30 to 0.60 per cent, adding defibrinated blood which was measured by drops The interpretation of the test was based on the discoloration of the supernatant fluid by free hemoglobin Ribierre¹² wrote a comprehensive critical review in 1903 summing up the progress made in the preceding thirty years He modified Hamburger's technic by standardizing many details

In the ensuing years, many more modifications of Hamburger's methods were introduced (Mosso,¹³ Viola,¹⁴ Widal, Abrami and Brulé,^{15 16} Ponder,^{17 18} Wiseman and Bierbaum,¹⁹ Lepeschkin,²⁰ Daland and Worthley,²¹ Beebe and Hanley,²² Creed,²³ Waugh and Asherman,²⁴ Dacie and Vaughan,²⁵ Hunter,²⁶ Berk,²⁷ Parpart²) Waugh and Chase²⁹ in 1928 described a method which combined the principle of counting unhemolyzed red cells in the hypotonic solutions-red cell mixture with the principle of measuring the amount of hemoglobin in the supernatant solution

The following are the most important features which have been modified by different authors

- 1 The type of anticoagulant used at first, defibrinated blood or fresh blood without an anticoagulant was used, later, oxalated, and still later, heparinized blood came to be preferred

- 2 The use of whole blood or washed red blood cells

- 3 The amount of blood and hypotonic solutions employed

- 4 The chemical composition, the number and strengths of the hypotonic solutions chosen Although most workers used solutions of sodium chloride, others selected solutions of other salts, such as sodium sulfate Simmel⁷ used six different salts, attempting to create a mixture similar to that existing in the blood Other investigators used serum from the same patient diluted in different proportions with distilled water¹⁹

- 5 The method by which the hypotonic solutions and blood were measured, many authors still using the drop as the unit for either or both solutions and blood, others using carefully standardized pipets

- 6 The method for determining the beginning and the end of hemolysis and the percentage of hemolyzed red blood cells in various dilutions of hypotonic solutions Gallerani³⁰ used the Fleischl hemometer to determine the percentage of hemolyzed erythrocytes In an attempt to obtain more accurate results, Ponder devised differ-

ent methods to determine the degree of hemolysis he first used a radiometer,¹⁷ later selenium¹⁸ and potassium photoelectric cells, and still later a Stufenphotometer.³¹ Waugh and Asherman²⁴ were apparently the first to use a photoelectric colorimeter for the measurement of the amount of hemoglobin present in the supernatant fluid in each tube.

7 The method of reporting results and, by some authors, of plotting them in graphic form. Many of the methods require the simultaneous performance of a control test from a known normal subject.

With various changes in method, many different results have been obtained so that the data of any one author for normal and pathologic conditions are seldom comparable to those of another. In most instances, all one can say is that the hypotonic resistance of the red cells is normal, increased or decreased.

II METHOD

A. Photoelectric determination of the degree of hemolysis

Our method is a modification of the photoelectric determination of erythrocyte fragility, as first described by Waugh and Asherman²⁴ in 1938, and later modified by Hunter²⁶ in 1940. The Evelyn technic for the determination of oxyhemoglobin is used. Since it is known that hemolytic systems are affected by small changes in the pH, temperature, oxygen and carbon dioxide contents, and by the age and the concentration of the red cells, we have attempted some standardization of these variants.

The stock solutions are prepared from freshly distilled water and chemically pure sodium chloride, using the analytic balance. Buffer salts are purposely omitted because the sodium or potassium ions present may affect the tendency of the erythrocytes to hemolyze. Solutions are prepared at percentage intervals of 0.04 between the concentration of 0.04 per cent and 0.20 per cent and between those of 0.52 per cent and 0.80 per cent sodium chloride. Between the concentrations of 0.20 per cent and 0.52 per cent the percentage interval between solutions is 0.02 per cent. The solutions are kept in glass stoppered bottles and the pH of sample solutions checked at two week intervals by the Beckman pH meter. The pH of the distilled water and the solutions was found to range between the two extremes of 5.5 and 7.0. When a variation from these two extremes occurred new solutions were prepared. The saline concentration of the solutions is checked by the silver nitrate method to insure its correctness. Solutions are made up in 500 cc. volume every four to six weeks, more frequently in the summer than in the winter, to compensate for greater evaporation, and are kept at room temperature. A series of 29 conical centrifuge tubes is set up in consecutive order, from 0 (i.e., distilled water) to 0.80 per cent NaCl. Using the same pipet, 10 cc. of each solution is transferred into the appropriately labeled centrifuge tubes. Errors resulting from dilution or concentration of solutions are minimal since these are pipetted always in the same order (see below) and a difference from one solution to the next is too small to result in a significant error.

From 2.5 to 5 cc. of blood are collected without stasis from a suitable vein, and

sufficient heparin is used to prevent coagulation for 4 hours * The vial of blood is gently rotated to insure complete oxygenation Exactly 0.02 cc of whole unwashed blood is delivered into each solution of NaCl by means of a standardized and calibrated Sahli 20 cu mm hemoglobin pipet After the blood has been pipetted into the salt solution, the pipet is filled once again with blood, which is discarded, and then again filled with blood for the next tube of salt solution

This is done in order to avoid hemolysis or dilution of the blood sample which might result from the fact that the pipet had become 'contaminated' by the salt solution It is advisable, when pipetting both the solution and the blood, to do so always *in the same order* so that whatever error results from lowering or raising the saline concentration will always be in the same direction in all tests Accordingly, we have pipetted the salt solutions by proceeding from the lower to the higher concentrations to avoid raising the saline concentrations, and we have pipetted blood by proceeding from the tubes in which no (or lesser) hemolysis is expected to occur to tubes in which greater hemolysis probably will take place

The tubes are inverted several times, left for one hour at room temperature, and then centrifuged at 1500 r p m for ten minutes The supernatant fluid from each test tube is carefully decanted and read in the Evelyn colorimeter for hemoglobin content, using filter No 540 Two perfectly matched absorption cells are used for all the readings The first cell contains the supernatant fluid from the 0.80 per cent tube, which is used as the blank, since no hemolysis usually occurs in this dilution, and the second cell is used to match the consecutive dilutions against the blank If there is any reason to suspect that hemolysis will take place, or has taken place at 0.80 per cent NaCl solution, a higher concentration of salt solution, 1 c, 0.85 per cent NaCl solution or 0.90 per cent, may be used for the blank

Bile pigments, or any other plasma constituents which might alter the light absorption, will not interfere with the reading since they are present in the blank in the same amount as in all the other tubes In any event, the use of the appropriate filter automatically eliminates the possible error deriving from the presence of chromogens other than hemoglobin

Several of the technics thus far devised include a 'correction' for anemia, which involves the use of a larger amount of blood or removal of a certain amount of plasma whenever anemia is present in order to include the same volume of red cells In our experience, fragility curves in both normal and abnormal subjects, using different amounts of blood, yielded curves with irregular variations which were within the limit of experimental error Alterations of erythrocyte fragility were by no means proportional to the degree of severity of the anemia Bloods with the same degree of anemia from patients with different conditions showed distinctly different types of curves For these reasons, and since the results of our tests are reported in terms of percentage of the total amount of red blood cells hemolyzed, 'correction' for anemia did not appear necessary and was, therefore, not carried out

* One drop of Roche Organon Heparin (Liquacmin) as delivered from a No 20 needle is used for each sample of blood

The use of washed red blood cells rather than of whole, fresh, unmodified blood has been a highly controversial issue since Widal, Abram¹ and Brulé¹⁶ showed that increased hemolysis to hypotonic salt solutions could be demonstrated in some patients whose unwashed erythrocytes yielded a normal type of fragility. Several investigations later indicated that washing the cholesterol off the red blood cells surface, as with a solution of sucrose, would result in an increase of erythrocyte fragility, whereas the removal of lecithin with Brinkman's solution would result in an increased resistance. The cholesterol lecithin ratio was considered as very important in this regard.

The above results could not be duplicated by other workers, who were unable to find any alteration in red cell fragility by washing erythrocytes with physiologic solutions (Saslow³²). Ponder and Saslow³³ established that washing rabbits' red cells with sodium chloride or glucose solutions isotonic with rabbits' plasma did not alter the volume of red blood cells. They stated that the concentration of such solutions should be of 1-12 per cent NaCl.

Ponder³⁴ studied the inhibitory effect of blood serum on hemolysis, but these investigations were performed on fragility to hemolytic substances like saponin, bile salts and sodium hydroxide, where an interaction between the hemolytic agent and various plasma components could be expected. These results therefore could not be applied to hypotonic salt fragility.

In our laboratory, parallel fragilities performed on whole blood and on washed red blood cells showed somewhat less resistance in the latter, perhaps because 0.85 per cent sodium chloride which was used for washing may be regarded as a slightly hypotonic solution. We finally concluded that the use of whole unmodified blood was preferable to that of 'washed' blood since it eliminated one step of doubtful value and since 'washing' might actually injure the red cells, thus making them hypotonically fragile. In certain cases of hemolytic anemia, greater erythrocyte fragility might possibly be demonstrated with washed than with unwashed red cells. This fact was first stressed by Widal, Abram¹ and Brulé. As yet we have been unable to confirm their results, although further studies on this point are in progress.

Variation in the fragility of the same subject from day to day was found, but this was never of sufficient magnitude to give a significant difference in the interpretation of the results. This confirms the findings of Whitby and Hynes⁸ in 1935.

B Method for plotting the curve of hemolysis

By plotting the per cent of hemolysis along the ordinate, against the decreasing strengths of saline along the abscissa, a sigmoid curve results. From inspection of the fragility curves as obtained by our method and of those of other investigators, it was noted that definite irregularities occurred in the rate of progression of hemolysis from tube to tube no matter how carefully the tests were performed. It was believed that in certain pathologic conditions these irregularities might represent changes in the 'thickness population' of the blood, not well demonstrated by the ordinary methods in use for graphic charting.

A method was therefore devised in which the 'hemolytic increments,' were calculated and charted. This was done by determination of the additional amount of hemolysis occurring in the successive tubes of hypotonic salt solution which

contained progressively diminishing saline concentrations. For example, if no hemolysis occurs at 0.56 per cent sodium chloride, and 10 per cent of the red blood cells hemolyze at 0.52 per cent, and 50 per cent of the red cells hemolyze at 0.50 per cent, the hemolytic increment (i.e., the increase in degree of hemolysis) is 10 in the 0.52 per cent solution and 40 in the 0.50 per cent solution. The hemolytic increments, when plotted, yield curves that are somewhat similar in configuration to those obtained with Price-Jones curves of red cell diameters. They are considerably more graphic and informative than those obtained with the ordinary methods for plotting photoelectric fragility.

The actual figures for drawing the new type of curve are obtained in the following manner:

1. By using conversion tables, change the photometer readings into grams of oxyhemoglobin liberated.

2. Calculate the per cent of blood hemolyzed in each tube by dividing the hemoglobin reading in grams in the 0 tube (i.e., the total amount of hemoglobin) by the hemoglobin reading in grams in each tube.

3. Find the hemolytic increment by subtracting the percentage of blood hemolyzed in the first tube from that of the second, the second from the third, etc.

4. Draw a curve, plotting the percentage saline solutions on the abscissa and the hemolytic increments on the ordinate.

By proceeding from the observer's left to his right along the curve, it is seen that by adding the value at any one point to the values of all previous points (left to right) we obtain the total amount of red cells which have been hemolyzed at that concentration of sodium chloride. In other words, the value of the percentage of red blood cells hemolyzed, appearing in the curve at *each* concentration of sodium chloride expresses only the percentage of red blood cells which was hemolyzed at that particular concentration of sodium chloride and which had not been hemolyzed in the previous solutions.

If practically all cells tend to hemolyze at one point (isohemolysis) a sharply peaked monophasic curve results but if, on the other hand, the cells are hemolyzed over a wide range of hypotonicity (anisohemolysis) a biphasic or multiphasic curve results. The data obtained from determinations in both normal subjects and in those with various types of blood dyscrasias, revealed that certain diseases followed a more or less definite pattern with respect to the shape of the plotted curve of hemolytic increments. It appeared probable that the curves gave a graphic picture of the red blood cell thickness population, at least with the thickness diameter ratio as a principal factor.

In addition to the graphic representation of the hemolytic increments the following features have appeared to us to be of significance: (1) the concentration of the solution which shows beginning hemolysis, (2) the solution in which hemolysis is complete (since in a number of cases, both normal and pathologic, 100 per cent of the red blood cells hemolyze only in distilled water, we have concluded that the solution in which 90 per cent of the red blood cells hemolyze is a more significant index of total hemolysis), (3) the solution in which there is 50 per cent hemolysis, this solution being defined as indicating the mean corpuscular fragility, (4) the breadth of the curve, (5) the height of the highest hemolytic increment.

FIG 3

FIGS 1, 2, 3 PHOTOELECTRIC HYPOTONIC FRAGILITY CURVES IN A NORMAL SUBJECT, A SUBJECT WITH HEMOLYTIC ANEMIA, AND A SUBJECT WITH SEVERE MEDITERRANEAN ANEMIA

The curves are charted both by the conventional method and by that using hemolytic increments. The *first* curve (normal) is tall, monophasic and narrow based with most hemolysis occurring between concentrations of 0.52 and 0.44 per cent NaCl. The *second* curve, (hemolytic anemia) is broader and with more than one peak. Hemolysis begins in physiologic salt solution and is practically complete at 0.52 per cent NaCl. The *third* curve (Mediterranean anemia) is low, broad and multiphasic with hemolysis beginning at 0.52 per cent NaCl, complete very close to distilled water.

Normal individuals almost invariably yielded monophasic curves. The breadth of the curve was less than 20 per cent, that is, most of the red blood cells (90-95 per cent) hemolyzed within solutions differing by only 20 per cent sodium chloride. None or very little hemolysis occurred in the 0.60 per cent solution. Less than 5 per cent hemolysis occurred in the 0.56 per cent solution.

The highest hemolytic increment occurred normally in one of the salt solutions between 0.52 and 0.44 per cent and represented 40 to 50 per cent of the red blood cells. The mean corpuscular fragility (the solution in which 50 per cent RBC hemolyzed) was normally at 0.50 or 0.48 per cent. Ninety per cent of the red blood cells hemolyzed above the 0.42-0.40 per cent solutions. As already stated in many subjects, both normal and pathologic, a further increase in hemolysis occurred at or close to the distilled water level. While no explanation for this can be offered, one can speculate that this is due to the presence of a certain number of "rev" red cells, i.e., reticulocytes, which because of their unusual thinness are unusually resistant to hypotonic solutions.

Figures 1, 2 and 3 are examples respectively of a normal curve, a curve

FIG 4

FIG 5

FIG 6

FIGS 4, 5, 6 PHOTOELECTRIC HYPOTONIC FRAGILITY CURVES WITH THE SIMPLIFIED (7 TUBE) METHOD IN A NORMAL SUBJECT, A SUBJECT WITH HEMOLYTIC ANEMIA AND A SUBJECT WITH MEDITERRANEAN ANEMIA

The curves show the range of hypotonic salt solutions in which hemolysis occurs with the typical shift to the right (leptocytosis) and to the left (spherocytosis) in the abnormal cases. These curves, although sufficient for most clinical diagnostic work, fail to give a detailed picture of the red cell population.

case of acquired hemolytic anemia, and a curve from a case of severe Mediterranean (Cooley's) anemia. The normal curve shows all of the above mentioned characteristics, i.e., the level at which hemolysis first takes place, the width of the base of the curve, and the height of the highest peak. The conventional type of hemolysis curve is also given for comparison. The curve from the case of hemolytic anemia shows a definite shift to the left (i.e., increased hemolysis in relatively concentrated solutions of NaCl) and a tendency to a very high peak as well as to a rather narrow base. The third curve, a severe case of Mediterranean anemia, shows a markedly broadened base, extending practically from the level at which hemolysis first begins in a normal subject, down to the distilled water level. The mean corpuscular fragility and the point at which 90 per cent of the red blood cells hemolyze shows a marked shift to the right. There are no high peaks but many small ones, indicating not only a great diversity in red cell thickness but indirectly a marked fault in the production of red blood cells of uniform degrees of thickness.

III SIMPLIFIED METHOD

After eighty cases had been performed in both normal and abnormal subjects, a simplified test for clinical purposes was devised. In this test the following solutions were used: 0.80, 0.56, 0.48, 0.44, 0.40, 0.32 per cent NaCl solution and distilled water. The 0.80 per cent solution was used as a blank since hemolysis of both normal and abnormal bloods did not usually occur in this solution. For the determination of total hemoglobin, distilled water was used. In the 0.56 per cent solution, normal subjects showed less than 5 per cent red blood cell hemolysis, a much higher percentage of hemolysis in this tube occurred in the various types of hemolytic anemia. The 0.48, 0.44, and 0.40 per cent solutions showed the greatest degree of hemolytic increment in normal subjects, 16, 45 to 75 per cent, 15 to 35 per cent, and 25 to 15 per cent respectively. The 0.32 per cent saline gave hemolysis of close to 100 per cent red blood cells in normal subjects, but of lesser degree in the abnormal states with increased hypotonic resistance.

The results of this simplified method were plotted in curves in the same manner as outlined above for the complete test. Figures 4, 5 and 6 are examples of 3 curves obtained with the simplified "seven tube" method in a normal subject, a case of hemolytic anemia and a case of Mediterranean anemia, respectively. The different characteristics of the curves are obvious at a glance, with the shift to the "left" in the case of hemolytic anemia, and the shift to the "right" in the case of Mediterranean anemia.

Several simplified methods, utilizing only two to four tubes, have been devised in the past for the purpose of obtaining prompt information as to the fragility of the red blood cells (Lepeschkin,²⁰ Berk,²⁷ and Smith³⁶). The use of seven tubes appears to be simple enough to allow for relatively quick performance. It is obvious, however, that it does not give the regular types of curves seen with the complete test, nor details as to the variations in red cell population. It thus appears to be unsatisfactory for investigative purposes, although as a clinical test it appears to have definite merit.

IV DISCUSSION

Ponder³¹ made use of two types of curves in his extensive studies. He used the term "time dilution" curve to designate the curve obtained by plotting the time required for *complete* hemolysis against each dilution of the lysis used. The percentage of red cells hemolyzed was plotted against time in the second type of curve which he called "percentage hemolysis." He was more interested in hemolytic agents such as saponin, and sodium taurocholate, than in hypotonic salt solutions. Besides, he always introduced the element of time for the hemolytic reaction to occur, and his investigations were for the most part limited to normal erythrocytes. Unfortunately, his contributions have not as yet found wide application in the clinical field.

Various investigators have questioned the importance and value of the shape of the curve obtained when quantitative methods for determining hemolysis are used. Thus Vaughan³⁷ expressed the belief that the curve of hemolysis shown by plotting the concentration of saline against the degree of hemolysis, both being

expressed as 1 percentage, utilizes 1 method which is clearly unsatisfactory, since markedly different curves may lie in the same range." Creed²³ in 1938 wrote "it was hoped that the form of a fragility curve constructed from the data obtained might show distinctive differences in various blood diseases and possibly in other conditions. For the most part these hopes have not been realized." He also stated that there was 1 slight difference in the shape of the curve in pernicious anemia.

According to Dacie and Vaughan,²⁶ "the shape of the curve or span of resistance is without great practical significance," and "study of the shape of the curve in pathological bloods is not in practice very useful." In a later publication, however, Dacie²⁵ paid more attention to the shape of the curves, classifying them as 'tailed,' 'diagonal' and of 'normal type.' Berk²⁷ agreed with the above statements of Dacie and Vaughan.

Waugh and Asherman,²⁴ as well as Hunter,²⁶ plotted their results in curves. However, Waugh and Asherman did not attach much importance to them. Hunter wrote "If the technique has been carefully carried out the curve will ordinarily be sigmoid in character. In some instances, particularly in the case of blood showing increased fragility, the curve may show more than one maximal slope. The significance of this occasional variation from the usual curve, however, is by no means clear, and requires further investigation."

Our results indicate that the shape of the curve obtained, particularly as modified by the use of the hemolytic increment method, is of great importance. With our method of plotting, one can readily distinguish between bloods showing spherocytosis and bloods containing target (1 e., thin) red cells. What is perhaps more important is recognition of the concept that the changes in hemolytic increment from tube to tube indicate the hemolysis of different groups of red cells, 1 e., differences in red cell population thickness. This in turn might indicate either different types of red cells from the standpoint of their production by the bone marrow or differences in the ages of groups of red cells, since it is our belief that the cells just delivered from the bone marrow, 1 e., the reticulocytes, are thinnest, and the oldest red cells the most spherocytic. The reason for the fragility "range" even in normal subjects is in all probability due to this age difference in red cells, the oldest ones hemolyzing at 0.56 per cent or thereabouts, the youngest at 0.40 or 0.42 per cent.

In normal subjects, a very sharp and regular type of curve is present indicating a relatively uniform type of red cell and of age thickness population. 'Little bumps' in the curve, particularly in the more hypotonic section of the curve, may be due to the presence of a certain number of relatively thin reticulocytes.

In subjects with Mediterranean anemia, the marked irregularity in the curve of hemolytic increments from tube to tube almost certainly indicates a marked variation in the type of red cell produced by the marrow. This brings graphically to light the fault in the red cell (and hemoglobin) production which appears to be at the basis of the disease. Thus, a careful reading of the hemolytic increment curves permits some insight not only as regards the variations in red cell population in given cases but also into the pathologic physiology of red cell formation.

itself. The use of the terms 'isohemolysis, anisohemolysis, shift to the left, shift to the right, broad base, etc.' appear to be of some value in describing the type of hemolytic curves obtained by this method, and thus in developing further insight into the physiopathologic mechanisms of blood destruction.

V. SUMMARY

A method is described for the determination and charting of the fragility of the red blood cells to hypotonic sodium chloride solution. For plotting the results obtained, a new method was used, employing the principle of "hemolytic increments," i.e., plotting the additional amount of hemolysis occurring in each successive tube of solutions of decreasing saline concentration.

By this method, curves are obtained somewhat similar to those of Price-Jones curves of red cell diameters. Such curves, when properly analyzed, afford an interpretation of the varying diameter thickness range of the red cell population and indirectly an insight into the types of red cells present, and of the possible hemolytic mechanisms present. Preliminary investigations indicate that they are particularly instructive in the hemolytic anemias and especially in the Mediterranean anemias.

A simplified shorter method was also devised for routine clinical use. This method, although not as useful for research purposes, has proved to be more accurate and yet less time consuming than most methods currently used.

EDITORIAL

HEPARINEMIA

EARLY workers on blood coagulation often used the terms anticoagulant and antithrombin interchangeably. Even today this tendency is still evident, especially in the writings of those who are more familiar with the chemical than the physiologic aspects of blood coagulation. Antithrombic substances are, of course, anticoagulants, but there are several anticoagulants which have no antithrombin activity. The first efforts designed to demonstrate the presence of heparin in the blood depended on the effect of addition of extracts of blood on the rate of coagulation and antithrombin activity of normal blood. The results were not striking.¹ When Chargaff² showed that protamine combined with heparin quantitatively, the way was open for an accurate method for the titration of heparin in the blood. However, the smallest amounts of protamine that can be added to normal blood and still produce an effect usually delay coagulation rather than accelerate it. The same may be said for toluidin blue and similar heparin-binding dyes. Jaques and Waters³ were unable to recover any heparin from as much as 4 liters of blood of normal dogs.

Moreover, heparin in low concentrations actually accelerates the coagulation of blood. This effect, first brought out by Fischer,⁴ has been confirmed both with natural heparin⁵ and a synthetic substitute.⁶ The amounts of natural heparin necessary are of the order of 0.001 to 0.01 mg per 100 cc of blood, well beyond the range of detection by protamine titration methods. There are no figures available regarding the concentration of heparin in the blood of man or intact experimental animals.⁷ Likewise, no heparin (or any other anticoagulant) has to date⁸ been found among the fractions separated from human plasma by the Cohn method.

It seems that, normally, heparin is contained within the mast cells of the tissues.⁷ Drastic cytolytic agents, such as are employed in its preparation, are necessary to release it from the cells.⁹ This probably explains why the blood of animals with neoplasms containing large aggregations of mast cells (mast cell tumors of dogs)¹⁰ displays no altered coagulation and contains no heparin, despite the fact that the yield of heparin from extracts of such tumors in the dog is fifty times that of extracts of the liver.¹⁰

The foregoing throws some doubt on the existence of heparin as a component of normal blood, or as its physiologic anticoagulant, but provides a basis for judging the significance of recent reports of the presence of heparin in the blood of man and experimental animals. *Heparinemia* would seem to be the proper designation for such a phenomenon.

In animals, heparinemia has been observed after intravenous injections of pepsin⁹ ascaris extracts and trypsin¹¹ in anaphylactic shock¹²⁻¹³ and after exposure of the body to massive ionizing radiation.¹³⁻¹⁵ These experimental findings made it seem highly probable that heparinemia might occur in man. A recent report of the presence of a heparin-like anticoagulant in the blood of patients treated with one

of the nitrogen mustards seems to be the first *convincing* demonstration of such an occurrence in man ¹⁴ No doubt, a greater awareness of such a possibility, and familiarity with the special technics necessary for the demonstration of heparin will lead to its being found associated with other clinical states. Heparin may conceivably be liberated during the explosive phase of certain severe systemic reactions, especially those involving widespread cytotoxicity. The unexpected, urgent, transient and fatal character of these reactions in man has made them, in the past, unsuitable for careful study.

Until lately, ¹⁴ spontaneously developed heparinemia did not constitute a clinical challenge. In patients receiving heparin because of thromboembolic disease, excessive bleeding occasionally has made it desirable to restore the coagulation of the blood to normal. Protamine injected intravenously (1 - 2 mg/Kg body weight) does this effectively, since this basic protein binds the acidic heparin quantitatively in a proportion of 2 to 1.

It is possible that spontaneously developed heparinemia may sometime become an important clinical entity and demand similar management. In the hemorrhagic phases accompanying acute leukemias, thrombopenias and aplastic anemias, some not altogether conclusive evidence has been offered that heparinemia exists ¹⁵ Therapeutic trials with protamine and toluidin blue (an antiheparin dye) have been made. In contrast with the experimental heparinemias following radiation, no convincing *direct* evidence has been brought out of the presence of heparin in the blood of patients with leukemia, thrombocytopenia and aplastic anemia. In our hands, protamine therapy has not altered significantly the hemorrhagic manifestations in these states.

Heparinemia should be looked for in clinical states accompanied by chronic widespread tissue necrosis. Conditions resembling those brought about by ionizing radiations may conceivably be produced by other pathogenic agents. However, anticoagulants other than heparin may be found in such states. Evidence has recently been advanced that entrance of anticoagulant substances into the blood or an increase in those already present therein ^{16 17} will alter the finely adjusted balance between anticoagulant and coagulant factors, to which the blood owes its fluidity and coagulability. Up to relatively recent times, absolute deficiencies in the coagulant factors (platelets, prothrombin, fibrinogen) were almost exclusively held responsible for diminutions in the coagulability of blood. The recently accumulated facts have served to modify this stand and to support what seems to be a more rational, though not as simple, explanation of the mechanisms underlying the maintenance of the fluidity and coagulability of circulating blood.

ANEMIA

EXPERIMENTAL FINDINGS IN LATENT SIDEROPENIC ANEMIA *E. Rothblin and E. Undritz* From the laboratory for experimental pharmacology of Sandoz S. A., Basle, Switzerland *Schweiz med Wschr* 1947 58-60

Sideropenic anemia is known as a definite disease. Experimentally the syndrome has been produced in the white laboratory rat and, as in human patients, was shown to respond to iron therapy. The authors found that normal hemoglobin findings do not always correspond to normal iron depot.

C. M.

DEVELOPMENT OF PERNICIOUS ANEMIA IN A CASE OF MICROCYTIC HYPOCHROMIC ANEMIA *F. Fierz* From the Medical Section of the Cantonal Hospital, Aarau, Switzerland *Schweiz med Wschr* 1947 1198-1199

A female patient with nanism of pituitary origin was under observation for hypochrome microcytic anemia. She developed during pregnancy by exhaustion of the intrinsic factor the hematologic picture of pernicious anemia.

C. M.

FOLIC ACID THERAPY: RESULTS OF A CLINICAL STUDY *W. S. Adams and J. S. Lawrence* From the Department of Medicine, University of Rochester School of Medicine and Dentistry and Medical Clinic of the Strong Memorial and Rochester Municipal Hospitals, Rochester, New York *Am J M Sc* 215 487-497, 1948

Thirty-four miscellaneous cases treated with folic acid are reported and correlated with other reports in the literature. The authors conclude that folic acid is effective in macrocytic anemia with a megaloblastic marrow, and in sprue. No effect was obtained in the anemia of chronic nephritis, leukopenic of Addison's disease or Felty's syndrome, idiopathic leukopenia, leukemia or leukopenia following irradiation. Again the statement is made that folic acid does not prevent the progression of the neurologic manifestations of pernicious anemia.

C. A. F.

LEUKOCYTES AND LEUKOCYTIC DISEASE

THE LEUCOCYTOSIS OF DIABETIC ACIDOSIS *J. L. Tullis* From the Department of Biological Chemistry, Harvard Medical School, and the Laboratories of Pathology, New England Deaconess Hospital, Boston, Mass *Am J M Sc* 215 424-426, 1948

The author has extended his interesting studies on the effect of variation in the tonicity of blood on the circulating leukocytes. In seven patients in diabetic coma, levels of hypertonicity were determined by freezing point depression measurements on defibrinated blood and compared with changes in circulating leukocytes. These patients showed a variation in molarity of their blood from 344 to 349 millimoles per liter on admission and after recovery a variation from 301 to 349 millimoles. White counts varied from 18,700 to 26,760 per cubic millimeter. There was a linear relationship between molarity and absolute numbers of circulating neutrophils. It is of interest that there were no eosinophils seen in the

smears of these patients when in coma, and that the same alteration in leukocyte pattern is seen in conditions of stress and after adrenal cortical stimulation. The author, however, has previously shown that these changes occur in circumstances where the adrenal cortex mechanism is not involved

REMARQUABLES RESULTATS DU TRAITEMENT PAR L'EXSANGUINO-TRANSFUSION D'UN CAS DE LEUCEMIE AIGUE (Remarkable Results of the Treatment of a Case of Acute Leukemia by Exsanguino-transfusion) *M. Bessis and J. Bernard*, Bull et mem Soc Méd d hôp de Paris 28, 29, p 871-877, 1947

The authors describe the case of a child, 6, with an acute leukemia with pyrexia, pallor, gum lesions, hemorrhages, hepatomegaly, splenomegaly, enlarged lymph glands, and with a typical blood picture 1,370,000 red cells, 86,000 white cells of which 98 per cent were lymphoblastic, and an abnormal bone marrow (99 per cent lymphoblasts). Transfusions were undertaken when the outlook was extremely grave and death appeared imminent. They were immediately followed by a marked and progressive improvement. In a few days the child's state was transformed, the physical signs disappeared and the blood and marrow returned to normal. The authors stress the following points: the diagnosis cannot be questioned. It was an absolutely typical acute leukemia, conforming to the classical descriptions. The rapidity and scale of the improvement are very remarkable. This child was moribund on admission to hospital. His state was so grave that the exsanguino-transfusion decided for the next day, was done during the night. From the first exsanguino-transfusion (only partial), the improvement was profound. After the second the child was transformed and, within a few days, apparently in excellent health. The progression of the improvement should also be noted. Not only was there a very marked improvement after each exsanguino-transfusion, but the maximum improvement was not reached at once. It continued during the days following the transfusion. This fact seems to counteract the idea that the treatment has only a palliative action. The final condition of the patient is worthy of attention: not only had the pallor, fever and hemorrhages disappeared, but also the liver, spleen and lymph glands diminished in size and after a few days became completely normal. There was also a progressive improvement of the blood and marrow. This favorable course was provoked by each exsanguino-transfusion. The first one allowed the patient to survive. The second caused a considerable regression of physical signs and a partial improvement in the condition of the blood and marrow. The third was followed by the return of the blood and marrow to normal. The authors do not believe that they have cured the child, but think that these early results allow hope that more will soon be known about the mechanism of the leukemia. The studies that they have undertaken may perhaps cause them to improve the method, possibly by the choice of special donors whose blood will contain the maximum quantity of the hypothetical antileukemic substance. It is possible too that the method will be applicable to other sarcomatoses, apart from the leukoses.

THE SKELETAL LESIONS IN LEUKEMIA. CLINICAL AND ROENTGENOGRAPHIC OBSERVATIONS IN 103 INFANTS AND CHILDREN, WITH A REVIEW OF THE LITERATURE. *F. N. Silverman*. From the Department of Pediatrics, College of Physicians and Surgeons, Columbia University, and the Babies Hospital, New York City. *Am J of Roentgenol* 59 819-844, 1948

The authors have reviewed the reports in the literature of skeletal changes associated with leukemia. They selected 131 well documented cases of leukemia of which 103 had been adequately studied roentgenologically. Data as to signs and symptoms, laboratory findings, and clinical course are included. Fifty-two of the 103 patients showed bone lesions. These were of four types: (1) transverse bands of diminished density (14 patients), (2) osteolysis (39 patients), (3) osteosclerosis (9 patients), and (4) subperiosteal new bone formation (17 patients). Approximately one half of these had bone pain.

The differential diagnosis presented by these patients is discussed. While some of the more general material in this article is of an arbitrary nature, the article provides a comprehensive discussion of the value of the roentgenologic examination in childhood leukemia.

C A F

MECHANISM OF URETHANE IN LEUCAEMIA. *S. Moeschlin*. University Clinic of Internal Medicine, Zurich, Switzerland. *Helvet med Acta* 14 279-294, 1947

Observations in healthy subjects under therapeutic doses of urethane during 14-32 days did not show

any notable changes in bone marrow. In chronic myeloid leukemia no evident changes in cell composition were found. Calculation of the mitotic index in leukemia cells showed a decrease of mitotic activity. The favorable action of urethane in leukemia is based upon a selective suppression of mitosis in the pathologic myeloblastic cells.

C M

A CASE OF FELTY SYNDROME WITH CYCLIC AGRANULOCYTOSIS *W. Löffler and C. Mauer*, University Clinic of Internal Medicine, Zurich, Switzerland. *Cardiologia (Basle)* XII 195-210, 1947.

A case of Felty syndrome is described characterized by a peculiar agranulocytic bone marrow reaction. During clinical observation of three years the patient showed recurrent agranulocytosis in a three weeks cycle. Splenectomy had no effect.

TWO CASES OF TULARAEMIA. TULARAEMIA AND INFECTIOUS MONONUCLEOSIS *V. de Lavergne, G. Favre, L. Blanc and P. Boissel*. *Bull. et Mem. Soc. Med. d. Hop. de Paris* 189-193, 1948.

Three days after they had skinned a hare which they found dead, two subjects presented simultaneously the following symptoms: fever, headache, asthenia, anorexia, numerous enlarged, tender lymph-glands, especially in the neck and the trapezoid regions. The spleen was palpable in one patient and enlarged to percussion in the other. One of the patients developed conjunctivitis, the other enlarged tonsils.

The diagnosis of a *Pasteurella tularensis* affection was confirmed in both cases by serodiagnostic test positive to 1/75 and reaching 1/2000 on the 45th day) and by guinea pig inoculation of a portion of a lymph gland and of a positive pharyngeal swab.

In both cases, treatment by streptomycin showed itself remarkably efficacious—apyrexia within 72 hours, disappearance of all symptoms within 8 days and rapid resolution of the conjunctivitis.

The diagnosis was facilitated by the occurrence of two simultaneous cases and by the contact with a suspect hare. Had the case been isolated, or had one been unaware of the contact with a hare, the clinical diagnosis would doubtless have been that of infectious mononucleosis. In fact, the number of leukocytes in each case was 8,000, with only 43 per cent of polymorphs in the first case and 37 per cent of polymorphs in the second. In both cases 6-7 per cent of atypical lymphocytes were found among the mononuclears.

The really interesting point was the occurrence in both cases of a Paul and Bunnell reaction positive to 1/112 in one and 1/896 in the other.

The two observations are however still troubling. Although the authors have studied the agglutination of *P. tularensis* in six cases of infectious mononucleosis and have found it constantly negative, when one is faced by the clinical picture of infectious mononucleosis, the possibility of tularemia should be kept in mind and enquiries made as to possible sources of contagion (particularly game).

J P S

MALIGNANT BONE AND BONE MARROW NEOPLASTIC TUMORS *K. Rohr*, University Clinic of Internal Medicine, Zurich, Switzerland. *Schweiz. med. Wschr.* 1947 207-215.

According to the authors' conception, leukemias are neoplastic manifestations of the hematopoietic organs. In the clinical course of these neoplasias he distinguishes a first phase of primary tumor, a second phase of hematogenic and lymphogenic generalization and, in leukemias, a third phase with propagation of cells in the blood stream. All bone and bone marrow tumors show early metastatic growth. In order to understand the biologic aspect of the different tumor types, it is necessary to consider the histogenesis. Besides the morphologic differentiation, certain physiologic aspects are of importance (increase of phosphatase in sarcomas, hyperproteinemia in multiple myelomas, increase of oxydase and porphyrins in leukemias). The author considers the reticulohistiocytic system as the genetic substrate for the myeloma cells and presumes a differentiation either towards plasma-cells or towards histiocytes. In leukemias he discriminates a myelocytic (chronic) variation, a promyelocytic (more subacute) and a myeloblastic (acute) variation based on the degree of morphologic differentiation of the cells. The myeloblastic leukemia more often has lymphogenic origin.

C M

PLASMOCYTOMA (MULTIPLE MYELOMA, KAHLE'S DISEASE) AND ITS ATTENDANT DISTURBANCES IN THE PROTEIN METABOLISM *W J Kolff and J Dhont* From the Municipal Hospital Engelenberg Foundation, Kampen, Holland *Am J M Sc* 215 405-410, 1948

The authors discuss a concept of plasmocytoma, based on recent articles in the Netherlands medical literature and on case studies. They have adapted Apitz's opinion that solitary plasmocytoma and diffuse plasmocytosis represent the same process. They question whether a local increase in plasma cells occurs and have always found a diffuse increase in plasma cells in cases of plasmocytoma. The importance of fresh preparations obtained either by sternal puncture or immediately after death in identification of plasma cells is stressed. They discuss the origin of Bence-Jones protein and feel that it is found specifically in this disease. Primary amyloidosis is felt to be a manifestation exclusively of plasmocytoma.

Some of these statements are open to question, in the opinion of the reviewer. A diffuse increase in plasma cells is found not infrequently in other diseases, and some caution must be exercised in making the diagnosis of plasmocytoma on such grounds. Likewise, one hesitates to accept the statement that all cases of primary amyloidosis are attributable to plasmocytoma.

HEMOLYTIC ANEMIA

AN ANTI-RH ANTIGEN-ANTIBODY REACTION FACTOR (THE RH PROTECTIVE FACTOR) PRELIMINARY REPORT *A Bloxson and R Matthaei* *Bull Johns Hopkins Hosp* 82 1-9, 1948

The authors believe they have demonstrated the presence of a factor in sera from Rh negative individuals which partially inhibits agglutination of Rh positive cells by Rh agglutinating antibodies. It is suggested that this inhibiting or protective factor may be active in vivo when Rh negative blood is used in the treatment of hemolytic disease of the newborn, and may at times be present in the maternal circulation and exert an inhibiting effect on the disease in the fetus. The observations on which these important assumptions are made appear rather tenuous and need confirmation.

R S E

THE LYSOLECITHIN TEST IN HEMOLYTIC ANEMIAS *C Maier* University Polyclinic of Internal Medicine, Zurich, Switzerland *Helvet med Acta* 14 470-474, 1947

Following the technic of Singer, investigations in hemolytic anemia were conducted. In anemia with secondary hemolytic action the lysolecithin-resistance is normal. In a case of severe subacute acquired hemolytic anemia with reduced osmotic resistance, the lysolecithin-resistance was distinctly increased. In cases of constitutional hemolytic anemia the lysolecithin-resistance is reduced. The same findings have been obtained in a case of chronic thrombosis of the splenic vein.

C M

EXPERIMENTAL HEMOLYTIC ANEMIA *W Baumgartner* University Clinic of Internal Medicine, Berne, Switzerland *Helvet med Acta*, 14 502-507, 1947

According to the proceeding of Damashek and Schwartz the author produced hemolytic anemia of the immune body type in guinea-pigs. For the first time he found in the histologic examination of the spleen large macrophage cells storing erythrocytes. Antibodies are supposed to act not only as agglutinins and hemolysins but also as opsonins. He also found parenchymatic cells containing erythrocytes in the liver. Similar finding could not be obtained in cases of constitutional hemolytic anemia.

C M

THE CRYPTOGENIC ACQUIRED HEMOLYTIC ANEMIAS *J A Fisher* From the Nuffield Department of Clinical Medicine, Radcliffe Infirmary, Oxford *The Quarterly Jr Med*, 16 245, 1947

Eighteen cases of hemolytic anemia are discussed under the three headings of miscellaneous, acquired hemolytic spherocytic jaundice, and hemolytic anemia with paroxysmal hemoglobinuria. The difference between the first two groups does not appear fundamental, since neither studies of longevity of transfused cells nor the Coombs test was used as a basis for separation. The Coombs test was found to be positive when done in one case. The report serves to stress further the infinite variety of patients with

hemolytic disease and the author makes 1 pertinent observation in the association of hemolytic anemia leukopenia, and thrombocytopenia, and states, It seems reasonable to postulate a similar rather than a dissimilar pathologic process to account for the deficiency in the other two components, the platelets and the neutrophils

R S E

A STATISTICAL STUDY OF THE HEMATOLOGIC VARIABLES IN SUBJECTS WITH THALASSEMIA MINOR *W N Valentine and J V Neel* From the Department of Medicine of the University of Rochester School of Medicine and Dentistry, Rochester, New York *Am J M Sc* 215 456-460, 1948

Differences in the peripheral blood picture between patients with Thalassemia Minor and control groups were studied. The difference was already apparent in childhood, and amounted to 2-3 grams hemoglobin per 100 cc blood. This difference was superimposed on the normal sex variation. The tendency to have an elevated erythrocyte count was also observed. While these data are not new, they serve to quantify the abnormalities in this condition.

C A F

THE SIGNIFICANCE OF THE PAUCITY OF SICKLE CELLS IN NEWBORN NEGRO INFANTS *J Watson, AW Stabman and F P Bilello* From the Department of Internal Medicine, Long Island College of Medicine Brooklyn, New York *Am J M Sc* 215 419-423, 1948

Sickle cell preparations were made on 226 consecutive Negro newborn infants and their mothers. There was an incidence of sickle cells of 8 per cent among the mothers and 8.4 per cent in the infants. A longer time was required to sickle the infants' erythrocytes, and infants' erythrocytes showed only 0.5 to 29.5 per cent sickling in contrast to 84-100 per cent in maternal blood. The authors suggest that this difference represents a chemical difference between fetal and adult hemoglobin. Sickling increased in one patient studied from 6-90 per cent over the first four and a half months, paralleling the expected disappearance of fetal hemoglobin. This focuses attention on the role of hemoglobin in the sickling process.

C A F

BLOOD CLOTTING AND HEMORRHAGIC DISEASE

THE FIBRINOPENIC DIATHESIS. THE MAJOR PSEUDOHAEOPHILIC AFIBRINEMIA AND THE HYPOFIBRINAEMIAS. THE FIBRINOGEN LEVEL IN HAEMORRHAGIC STATES *P Croizat, L Revol and J Favre-Gilly* Lyon, France *Sang* 19 26-35, 1948

The authors studied the fibrinogen levels in sixty cases with haemorrhagic syndromes. They distinguish three primary groups of hypofibrinemias.

(1) An idiopathic hypofibrinemic diathesis with a fibrinogen level between 1 and 2.5 gm (méthode pondézale) responsible for certain recurring hemorrhages, such as epistaxis, vitreous hemorrhages, metrorrhagia, etc.

(2) Hypofibrinemias of hepatic origin.

(3) Finally, the authors report three cases of pseudohemophilic afibrinemia with fibrinogen levels less than 0.5 gm. Clinically, this more or less total absence of fibrinogen may be suspected by the sign of the microclot.

This work has been developed in an important study by Favre-Gilly (Paris, Publ. Vigot Freres 1947) in which he deals with the whole problem of the fibrinopenias.

The only point which seems to us to need discussion, concerns the hypofibrinemias. A level of 2 gm of fibrinogen is often found in normal subjects. On the other hand, the fact that a fibrinogen level of 1.5-2 gm coincides with localized recurring hemorrhages does not seem to us to be proof that it is the cause of these phenomena.

J P S

STUDY OF THROMBOCYTES WITH THE ELECTRON MICROSCOPE *M Bessis and M Burstein* Paris *Rev d hemat* 3 48-68, 1948

The authors describe the technic of their examinations in order to observe the platelets in their cir-

culating form, as *in vivo*, they took the blood with a paraffined needle and put it directly into a citrate solution containing 1 per cent formol

In order to observe the transient resting forms, already described as seen under the ultra-microscope by Fonio and Schwedener, they put the blood into citrate or oxalate solution

In both cases the plasma is centrifuged for three minutes at a speed of 2000 r p m. One drop of the plasma is then spread on a slide and covered with collodion, before dissolving glass with hydrofluoric acid. The fine particles of collodion which are to be deposited on the objective of the electron microscope are then dispersed.

Under these conditions, the circulating forms appear perfectly round with a central, very dense, nucleus and occasionally several granules.

In the transitional or dendritic forms, one observes the dendrites which can be seen on many microphotographs (magnification $\times 10,000$).

Finally, the resting forms appear as a layer of round cells with a very fine cytoplasm and a slightly condensed granular nucleus.

Goose thrombocytes were examined by the same technique.

The authors draw attention to the internal structure of the platelets which are formed of interlacing fibres around tiny spheres, and also to the little spherical bodies found in the plasma during the pre-coagulation period and of which the significance is still unknown.

NEWS AND VIEWS

INTERNATIONAL SOCIETY OF HEMATOLOGY

The International Society of Hematology in its first full dress Congress met at Buffalo, August 23-27. There were 680 registrants from 18 different countries, including large groups from the Latin American countries and several individuals each from Great Britain, France, Holland, Sweden, Denmark and Norway.

The meetings were fully attended and the numerous exhibits and papers proved to be of unusual interest. Those attending the meetings were highly enthusiastic not only because of the high calibre of the papers and the discussions but for the opportunity for face to face discussion with the various groups of workers in the field of hematology throughout the world.

The first day's program was devoted to hemorrhagic disease and included papers by Diamond (Boston) on Congenital Afibrinogenemia, Soulier (Paris), Prothrombin Consumption, Seegers (Detroit), Prothrombin Activation, Owren (Oslo) on Factor V, Lozner (Syracuse) and Pavlovsky (Buenos Aires) on Hemophilia, Macfarlane (Oxford) on Prothrombin, Tocantins (Philadelphia) on Antithromboplastin, Jacques (Saskatchewan) on Heparinemia, and Bernard (Paris) on Thrombocytic Dystrophy.

The second day's program dealt with erythropoiesis and anemia and included papers by Bethell (Ann Arbor) on PTAH, Daft (Bethesda), Experimental Anemias, Jacobson (Cambridge, England), Enzymatic Activation of Folic Acid, Tinsley and Moore (St. Louis), Inhibition of Erythropoiesis by High Oxygen Concentration, Finch (Boston), Iron Metabolism in Hemochromatosis, Shemin and London (New York), Porphyrins, Chevallier (Paris) Hemolytic Anemia.

On the third day, Jones (Buffalo) discussed phase microscopy and histochemical methods, Gibson and Vallee, Zinc and Carbonic Anhydrase, Thorell (Stockholm), Cytochemical Aspects of Blood Cell Development, Gonzalez-Guzman (Mexico), Ictero-Anemia, Farber (Boston) Aminopterin in Leukemia. This last paper evoked a great deal of discussion.

On the fourth day, iso-immunization was the chief topic of discussion, with papers by Houghton (Columbus), Mourant (London), Levine (Raritan), Reid (Dallas), van Loghem (Amsterdam), Young (Rochester, N. Y.), Race (London), Dacie (London), Robb Smith (Oxford), and Bessis (Paris).

Thirty-eight scientific exhibits on display throughout the sessions dealt with lymph node aspiration, marrow puncture, red cell abnormalities, folic acid antagonists, hemolytic transfusion reactions, sludged blood, multiple myeloma, phase microscopy, electron microscopy, P₃₂ therapy, spleen and hypersplenism, Rh factor, vitamin B₁₂, etc.

The following officers were elected

President Professor Sir Lionel Whitby, Cambridge, England

Vice-Presidents For North America Dr. William Dameshek, Boston

For South America Dr. Luis Sandoval S., Santiago, Chile

For Europe Dr. G. DiGuglielmo, Naples, Italy

Counsellors (To be elected from each country) The three counsellors elected for the United States were as follows

Charles A. Doan, Columbus, Ohio

Edwin Osgood, Portland, Oregon

Ernest Witebsky, Buffalo, New York

The next congress of the Society will be held in Cambridge or Oxford, England in 1950.

In the Constitution, which was formally adopted, it was stated that the requirements for membership for those having the M.D. or Ph.D. degree include a sustained interest in some phase of hematology of at least five years' standing.

BOOK REVIEWS

Il Principio Antianemico-Pernicioso By G. ASTALDI AND M. BALDINI. Monograph of *Il Farmaco*, January 1948. pp. 234.

This monograph offers a rather complete review of what has been accomplished and written on the subject of antipernicious anemia preparations since Minor and Murphy's fundamental discovery in 1926.

The main interest of the authors seems to be in the various methods for standardization and dosage of antianemic preparations. They find that no method so far suggested is completely satisfactory and propose a test of their own. This consists of studying the reduction in size of nucleated red cells as the transformation of megaloblasts into normoblasts takes place in the marrow of patients with pernicious anemia. Two marrow samples are obtained and studied, one before administration of the material to be tested and one on the sixth day after it has been administered. They feel that from a therapeutic standpoint the antimegaloblastic unit corresponds to the antianemic unit (U.S.P.).

The work is well up to date with a short chapter on folic acid and other products which have appeared recently. This part of the work could profitably have been more extensive.

DAVIDE LIMENTANI

Cytologie Sanguine Normale et Pathologique By M. BESSIS. Paris, Masson & Cie, 1948. pp. 298.

With this work, Bessis offers the student of hematology in a pleasant and attractive fashion the old subject of morphologic hematology much too often cast aside today.

This achievement has been accomplished through a limitation of theoretic considerations and elimination of speculative and polemic discussions. The descriptive part of the text is maintained on a plane of reality and is clarified by the large number of black and white figures and by 19 colored plates. The illustrations, in the form of black and white half tones and of colored tables, are in general good and some are particularly fine.

The material is divided into ten chapters devoted to cytologic techniques, reticulo-endothelial system, quantitative study of the cells of blood and hemopoietic centers, stem cells, erythrocytic, granulocytic, thrombocytic, lymphocytic and histiocytic series and to the cells accidentally found on the smear of blood and hemopoietic organs. Each chapter includes a section on the morphology of pathologic changes involving the subject under discussion. Instructions for puncture of lymph nodes, spleen, liver, tumors, masses, etc., and information concerning normal and pathologic morphologic findings are given. The American reader may not care for the often involved European glossary.

This work does not include any information regarding phase microscopy and histochemical methods which are becoming so much a part of morphologic hematology. The book may be regarded as a valuable addition to the morphologic hematology library.

DAVIDE LIMENTANI

Maladies du Sang et des Organes Hematopoietiques By JEAN BERNARD. Paris, Editions Medicales Flammarion, 1948.

This beautifully printed and illustrated book of over 1000 pages represents one volume of a loose leaf system of medicine. There are many colored plates of blood and bone marrow cells. The various hemologic disorders are classified in a rather unusual fashion: those of acute type, those which are chronic (including pernicious anemia, polycythemia, chronic leukemias, etc.), those of constitutional or genotypic type, and those caused by various known factors such as infections and parasites. The whole work is carried out very simply and systematically, perhaps too systematically. There is very little stress placed upon fundamental physio-pathologic principles. The book is recommended for practitioners who wish to obtain a quick and authoritative review of a particular subject, systematically and lucidly presented.

CYTOLOGY OF RABBIT THYMUS AND REGENERATION OF ITS THYMOCYTES AFTER IRRADIATION, WITH SOME NOTES ON THE HUMAN THYMUS

By HAL DOWNEY, PH D

With the assistance of RUBY ENGSTROM, M A , M D

IT IS now generally conceded that the "thymocytes" are lymphocytes having an embryonic origin in the mesenchyme surrounding the epithelial anlage of the thymus, as shown by Maximow,^{1 2} Hammar,³⁻⁶ Hartmann,⁷ and others. A few investigators (Fulci,⁸ Goldner,⁹ Dustin,¹⁰ Schaffer,¹¹ Stohr,¹² Pappenheimer,^{13, 14} Winiwarter,¹⁵ Gottesman¹⁶ and Jaffe^{17 18}) have derived the free thymus cells from the epithelium, believing that they are special parenchymatous elements of the organ and not lymphocytes, or they are genuine lymphocytes derived from the epithelium (Schaffer,¹¹ Prenant,¹⁹ Gottesman¹⁶ and Jaffe^{17 18}). However, investigations of the embryonic development of the thymus, especially the detailed studies of Maximow^{1 2} and Hartmann,⁷ and experiments with radiation, transplantation, tissue culture, etc., (Dantschakoff,²⁰ Hammar,³⁻⁶ Jolly,²¹ Popoff^{22 23}) have convinced most investigators that the thymocytes are true small, medium and large lymphocytes identical to those of the lymph nodes, and that, like the latter, they are derived from mesenchymatous tissue.

As the normal thymus does not have germinal centers and lymph nodules it can be assumed that most of the lymphocytes of the adult organ, the majority of which are small lymphocytes, are descendants of the large lymphocytes which invade the epithelial anlage from the mesenchyme of the embryo. (Hartmann⁷ (1915) states that the immigration of these large, basophilic, ameboid lymphocytes begins at about the fifteenth or sixteenth day in the rabbit fetus, and that it subsides gradually. Transformation of these cells to small lymphocytes begins on the nineteenth fetal day, and all intermediate stages in the transformation are present between the nineteenth and twenty-fifth days, after the epithelial anlage has been completely penetrated by the large cells.)

Maximow^{1 2} saw many of these first large lymphocytes in mitosis and concluded that the production of small cells was largely by division of the large ones. (Hartmann⁷ could not determine the exact mechanism and seemed to assume that there

From the Department of Anatomy, Medical School, University of Minnesota, Minneapolis, Minn

is direct transformation of large to small cells. Many of the latter were in mitosis which, she thought, proved that they were not all derived from large lymphocytes.

To what extent the local stroma can contribute new lymphocytes, especially in the adult, is somewhat uncertain. The question is important from the standpoint of the maintenance of lymphocytes in the normal organ and their regeneration following pathologic involution. It was the main problem in the present investigation.

That the bulk of the supporting stroma is composed of an epithelial remnant of the embryonic anlage has been shown in detail by Hammar,³⁻⁶ Maximow^{1, 2} and Hartmann.⁷ The epithelium becomes disorganized by the immigration and proliferation of lymphocytes and assumes a superficial resemblance to the reticulum of lymph nodes. Hart²⁴ (1912), Rudberg²⁵ (1907), Pappenheimer¹³ (1910), Hammar,³⁻⁶ Ssyssojew²⁶ (1924), Wituschinski²⁷ (1926), Marine²⁸ (1932) claim that this epithelial 'reticulum' can form histiocytes, macrophages and giant cells, but the conclusion of Schaffer¹¹ and of Gottesman¹⁶ and Jaffe^{17, 18} (1924) that this tissue can also produce genuine lymphocytes is denied by the above authors and most other students of the problem. Ssyssojew,²⁶ who studied accidental involution in children, concluded that the cells of the epithelial reticulum behave exactly like those of the reticulo-endothelial system, and that they should be included with this system in spite of their different origin.

The problem is difficult because mesenchymatous tissue becomes mixed with the epithelial portion and it is usually impossible to distinguish the two tissues in sections of the late fetal and adult stages.

Fibers, interpreted as connective tissue fibers, were seen in the thymus by Watney²⁹ (1882), Bell³⁰ (1906), Mietens³¹ (1909), Pappenheimer¹³ (1910), Salkind³² (1912), Hartmann⁷ (1915), Strandberg³³ (1918), and Jolly²¹ (1923). Their presence except for those radiating from septa and blood vessels is denied by Badertscher³⁴ (1915). Strandberg,³³ using the Bielschowsky method, made an intensive study of the fibers in the human thymus from fetuses, newborn and adults up to the age of 54. He found that the black silver-staining fibers increased with age. They were most abundant in the medulla and the boundary between cortex and medulla. They radiated from the septa and from the blood vessels which penetrate the organ, and they penetrated the medulla for considerable distance beyond the vessels and septa. He could not determine relationship of fibers to cells and could not distinguish between epithelial cells and mesenchymatous reticular cells. The article is accompanied by excellent lithographed plates. The writer's preparations of rabbit thymus stained with azo-carmin show practically identical relationships of the blue-staining fibers to parenchyme as those described by Strandberg for the human thymus.

Mietens³¹ (1909) had observed numerous fibers penetrating the epithelial reticulum of the medulla in human and animal thymus from deep ends of septa and from perivascular tissue. The fibers become embedded in this reticulum but they do not contribute to its formation. Numerous thin fibrils in the cellular reticulum were thought to be precollagenous, while the thicker ones derived from septa and perivascular tissue of the larger vessels, and stained blue with Mallory, are collagenous.

Jolly,²¹ in 1923 and earlier, agreed that the thick fibers are collagenous. He could not stain the thin fibrils of the epithelium with Mallory's connective tissue stain, but could stain them with iron hematoxylin after prolonged mordanting, and so interpreted them as mitochondrial formations similar to those of the epidermis.

Investigations of others show that, mixed with the epithelial stroma there is a certain amount of mesenchymatous tissue which is undoubtedly responsible for the production of the reticular fibers. The problem was studied by Salkind³² (1912), Mollier³⁵ (1913), and in great detail by Hartmann⁷ (1915) who investigated the histogenesis of the rabbit thymus. Hartmann found that mesenchyme penetrates the embryonic anlage with the connective tissue septa and the blood vessels. At first it can be distinguished from the epithelium but later this distinction is impossible. As capillaries develop throughout the organ she assumed that they must be accompanied by mesenchyme which has the capacity to form new lymphocytes. During development of the thymus the narrow connective tissue septa contain numerous lymphoid cells and this tissue becomes a true lymphatic tissue, while the tissue surrounding the lobules remains as an ordinary connective tissue. She noted that the boundary line between the epithelium and the lymphatic tissue was soon obliterated and that the two tissues intermingled, a large portion of the septal tissue becoming a part of the organ parenchyme. She believed, but could not prove, that the mesenchymatous reticulum continues to form lymphocytes. One of the important conclusions from this work was, that the thymus stroma contains much more mesenchymatous tissue than generally had been assumed.

Salkind³² stated that he could see lymphocytes budding from the mesenchymatous reticulum within the thymus of the adult.

Tschassownikow³⁶ found it impossible to distinguish the two tissues except in tissue culture, where they separate.

Popoff²³ (1928), a student of Maximow's, investigated rabbit thymus by the tissue culture method. He found that the epithelium formed islands and a border at the edge of the lobules. Some of its cells became isolated from the syncytium, but they never phagocytized or stored colloidal dye. Later the epithelium degenerated and lymphocytes, histiocytes or myelocytes were never formed from it. Histiocytes were numerous in the earliest cultures. They were derived from the connective tissue partitions between the lobules, and in the interior of the organ, from undifferentiated mesenchyme cells about the blood vessels. Undifferentiated mesenchyme was found everywhere in close association with the blood vessels, and it is this tissue which produces histiocytes and lymphocytes in the autotransplanted thymus and during regeneration following radiation.

Emmart³⁷ (1936) also experimented with tissue cultures of embryo beef and human thymus and of 3-7 week old rats. She found that the outgrowth of epithelial reticulum could be distinguished from that of the mesenchymatous reticulum. The cells of the latter were smaller than those of the former and their nuclei were different. The epithelial reticulum formed sheets of cells in the later cultures. In two or three days after subculture there was an outgrowth of epithelioid tissue which differed from the outgrowth of the other two tissues. Its narrower bands had a distinct margin composed of fibroblast-like cells. Later some of the epithelioid

tissue broke up into individual round cells. This tissue was assumed to be a remnant of the original epithelium which had not been transformed to reticulum. No proof was offered for this conclusion.

From the foregoing statements from some of the literature it can be asserted that the thymus does contain a considerable amount of mesenchymatous tissue mixed with the epithelial stroma and that it is probably this tissue which produces the fibers described by numerous authors. From the character of the fibrils and from its activity in the production of histiocytes and lymphocytes (Popoff^{22, 23}) it can be concluded that this tissue is similar to the reticulum of lymph nodes, or that it is an undifferentiated mesenchyme closely associated with the vessels, as claimed by Popoff.

The writer was interested in determining whether the mesenchymatous reticulum can be distinguished from the epithelium in imprints or smears of the organ, and, if it can, to what extent it contributes to the formation of new lymphocytes in the normal organ and during regeneration following irradiation. He was also interested in studying the thymus lymphocytes in imprints, an interest which was stimulated by Dr. Arthur Kirschbaum, who showed him some very immature lymphocytes in imprints of the normal mouse thymus.

Pinner²⁴ (1915), a student of Pappenheimer's, seems to be the only one who has made a detailed cytological study of the thymus by the smear method. His interest was focused largely on the question of whether the small thymus cells are lymphocytes or epithelial derivatives.

The origin of myelocytes and mature granulocytes of the thymus was another problem studied in the present investigation. Their presence in the thymus has been described many times but there is no agreement on their origin. Some, like Hart²⁵ and Fulci,⁸ believe that they immigrate from the blood or connective tissue. Hart saw scattered eosinophil myelocytes in the human thymus, but believed they were the result of special conditions rather than an indication of hematopoiesis. He thought the blood was the most likely source. Wituschinski²⁷ (1926), experimenting with the introduction of foreign bodies in the thymus, derived them from adventitial cells of the vessels and from "hemocytoblasts," some of which originated from the epithelial stroma.

The prevailing theory for the origin of the thymus myelocytes is that they are derived from the lymphocytes of the organ. Maximow¹ (1909) described the development of myelocytes from large lymphocytes of the thymus of fetal rabbit and other animals. Danchakoff²⁰ (1916) showed a similar origin in the thymus of chick embryos after implantation of spleen grafts on their allantois.

Weidenreich and his student Weill made a detailed study of this problem. The main features were published by Weidenreich²⁹ (1912) and the details by Weill³⁰ (1913). Their material was taken from full grown rats and from 4 normal human subjects, aged 15, 17, 19, and 37 years. The 19 and 37 year olds were executed and the material was placed in the fixing fluid immediately afterwards. The other 2 were cases of accidental deaths.

The rat thymus was valuable because of the ring-shaped nucleus in the hetero-

phils and eosinophils which facilitated the study of the development of these cells from lymphocytes. All transitional stages in the process could be seen. The thymus cells also developed to plasma cells. The basophils were of the tissue type and were located in the connective tissue only.

The thymus from all 4 human subjects contained neutrophil and eosinophil myelocytes. Eosinophils were seen in every section, and even in the 37 year old subject about 35 per cent of them were myelocytes. The nuclei of the myelocytes varied from large leptochromatic to small pachychromatic nuclei similar to those of the small cells. Many myelocytes were in mitosis. Transitions between lymphocytes and plasma cells were seen also in the human thymus, and a few plasma mast cells were noted. Other mast cells were of the tissue type.

The authors concluded that the free round cells of the thymus are genuine lymphocytes of various sizes similar to those of lymph nodes. All types of lymphocytes, even the small ones, can develop to granulocytes and plasma cells within the thymus, and this is a normal process at all ages.

The authors did not mention the possibility of the development of granulocytes from mesenchymatous tissue located within the limits of the thymus parenchyme.

Pinner³⁸ made smears from the human thymus of 25 cases ranging in age from newborn to one year, and from one 8 week old rabbit. Two types of myelocytes were seen. One type had large, pale nuclei and was identical to the marrow myelocytes, the other type had small, dark lymphocytic nuclei. Both forms occurred in the promyelocyte stages with few granules. Pinner assumed that they were derived from lymphocytes, but he did not give any of the details.

Hartmann⁷ saw some myelocytes with nuclear structure similar to that of large lymphocytes in sections of rabbit thymus. She derived the granulocytes of the organ from large lymphocytes, but was not certain that they were of local origin, because she could not find eosinophil myelocytes containing only a few granules and because the neighboring connective tissue contained many granulocytes.

Ssyssojew²⁶ saw extensive myeloid metaplasia during pathologic involution in 15 children who had died of infectious diseases. The neutrophil promyelocytes were identical to the large lymphocytes except for the presence of granules in their cytoplasm. There was also myeloid metaplasia in the surrounding connective tissue, and in nearby vessels which had its beginning with large lymphocytes. Neutrophils were the most numerous granulocytes.

Popoff²² (1926), in regenerating stumps remaining after partial extirpation and of transplants, noted the formation of lymphocytes of different sizes from the connective tissue which invaded the hypertrophied epithelium with the vessels. Some of these lymphocytes developed to myelocytes which were mostly of the darkly nucleated, micromyelocytic variety.

Fulci⁸ (1913) stated that the thymocytes are not lymphocytes because they do not differentiate to plasma cells or granulocytes. However, the foregoing extracts from the literature indicate that there is good evidence for the origin of granulocytes from these cells, and Schaffer,¹¹ Weidenreich³⁹ and Dantschakoff²⁰ showed that they can form plasma cells. As the material studied by the writer contained many

myelocytes in both sections and imprints it was felt that renewed study of this question might be of interest. The imprints seemed to be of special importance because they showed the finest details of nuclear structure, which is a valuable feature in determining the origin of cells.

MATERIALS AND METHODS

The animals used were 10 newly born rabbits and 2 young normal rabbits, age 4 or 5 months. One young rabbit, aged 4 or 5 months, was irradiated with a dosage of 500 r u. This animal was killed on the sixth day after irradiation. Its thymus was large. One old rabbit was given 400 r u and killed eight days after irradiation. Its thymus was in an advanced stage of involution and showed epithelial hyperplasia. One old normal rabbit was not irradiated.

Some human material was also used for imprints. The specimens were from 2 full term newborns, 2 stillborns who died shortly before birth, one 2 year old male, one 5½ months fetus, and one premature aged 6½ fetal months.

Sections and imprints were made from all of these animals and imprints from the human material. Sections were stained with hematoxylin and eosin, Dominici's eosin-orange G-toluidin blue, and with Pappenheim's methyl green and pyronin. A few were stained with azocarmine for study of the distribution of connective tissue fibers. Sections stained with methyl green and pyronin were dehydrated with dioxan, as suggested by Miss Helen Harris of this laboratory. Retention of stain was much better than with the usual acetone or alcohol dehydration.

The imprints were made by touching a cut surface of the organ to a slide without smearing. The preparations were dried rapidly by waving them through the air, rapid drying being essential for good films. All imprints were stained with the May-Grunwald Giemsa combination. The Giemsa stain was used in double strength, 6 drops of stock solution in 3 cc. of distilled water for each slide for five or six minutes. The May-Grunwald solution was used like Wright's stain, one minute in the stock solution and three minutes after the addition of water. The diluted stain was poured off and the Giemsa added without rinsing. The slides were not covered because it was intended to use only the oil immersion objective. Most of the imprints showed some portions that were good for cytological study.

OBSERVATIONS (RABBIT)

The irradiated animals were used for the study of regeneration of lymphocytes in the thymus, the others for detailed study of the lymphocytes and of cells from the epithelial and mesenchymatous reticulum and for the granulocytes.

There was little histologic or cytologic difference between the thymuses of the newborn animals and those from the young adults, aged 4 or 5 months. In the newborn there were, however, fewer large lymphocytes and, in the imprints, more epithelial cells than were seen in the young adults. The presence of more epithelial reticular cells in the imprints of the newborn probably was due to the delicate texture of the organ which caused more of the epithelial cells to adhere to the glass.

EPITHELIAL AND MESENCHYMATOUS RETICULUM

In the imprints, the mesenchymatous cells usually could be distinguished from those of the epithelium, as shown in figures 5, 6 and 7 from newly born rabbits. Figures 5 and 6 are epithelial cells and figure 7 is a mesenchymatous cell identical to the reticular cells of lymph node imprints. The epithelial cells have rather sharp outlines when they are free and their cytoplasm is of a translucent pale blue color when stained with May-Giemsa. It is not completely homogeneous, for some areas

are slightly more basophilic than others, and it usually contains many small vacuoles seen best in the darker areas. It does not have the larger vacuoles usually present in the mesenchymatous cells or inclusions of phagocytized material in the normal animals.

Figures 5 and 6 illustrate variations in structure of the nuclei of the epithelial cells of the imprints. As seen in figure 5, the chromatin has a rather uniform distribution in the form of a network of broad strands which do not stain very intensely. This network may become more sharply defined and there may be some clumping of chromatin, as seen in figure 6. Nucleoli were not seen in the imprints, but in sections many of the epithelial cell nuclei contain a sharply defined spherical nucleolus which, with Dominici's stain, is colored light pink while the chromatin is blue. Pinner³⁸ saw nucleoli in some of the epithelial cells of imprints of human thymus. The nuclear membrane is extremely thin and poorly defined.

In the imprints the nucleus is round (fig. 6) or slightly irregular in shape, and in many of the cells it has a deep groove on the surface (fig. 5). These nuclear grooves also are seen in the sections, especially in the inner portion of the cortex and in the medulla, where the shape of the nucleus tends to be more irregular than in the outer portion of the cortex. In the latter region the nuclei are usually round or elliptical. In the sections the chromatin is condensed to a few scattered small granules which do not condense around the nucleoli. This results in an extremely pale nucleus with any of the stains used. The cytoplasm also shows very little affinity for any stain.

Cells like those of figures 5 and 6 are not numerous in the imprints, probably because they are not easily detached from their fixed position. They are most numerous in the imprints from the newborn animals. Many of them are damaged in the imprinting but usually can be identified by their peculiar cytoplasm in case the nuclear damage is too extensive.

The imprints do not have many histiocytic reticular cells like the one of figure 7 but there are enough of them to indicate that they are an important constituent of the stroma. They are identical to the reticular cells of imprints of lymph nodes illustrated by Sundberg and Downey⁴¹ (1942) in their figure 7, and in figure 4 of Downey and Stasney⁴² (1936). They are not fibrocytes of the septa or surrounding connective tissue because fibrocytes do not show the pronounced stippling of the nuclear chromatin of reticular cells and their cytoplasm is more homogeneous.

The reticular cell of figure 7, and others like it, differs in both nucleus and cytoplasm from the epithelial cells of figures 5 and 6. The cytoplasm has a pinkish cast due to the presence of numerous small azurophilic granules. It usually contains several large vacuoles, often with inclusions of phagocytized material. It seems to be more fluid in texture than that of the epithelial cells, for it usually extends for some distance beyond the nucleus and flows between neighboring lymphocytes, as seen in figure 7.

The nucleus stains darker than that of the epithelial cells because the chromatin is condensed in the form of small granules which gives the nucleus a stippled appearance. There are some open spaces in which the violet parachromatin is conspicuous. There may be some clumping of the chromatin granules to form chroma-

† All figures are from thymus of rabbit. All were painted with the same magnification, Leitz $\frac{1}{4}$ oil immersion objective and ocular $10\times$. Camera lucida outlines. The imprints were stained with May Grünwald Giemsa and the sections with Dominici's eosin orange G toluidin blue.

FIGS. 1, 2, 3. Pseudoc eosinophil promyelocytes and metamyelocyte. Imprint from 5 day-old rabbit. In fig. 1 the nucleus shows some stippling of chromatin that is characteristic of cells of the mesenchymatous reticulum, like the one of fig. 7, suggesting origin of granulocytes from this reticulum. Such an origin as seen in sections is illustrated in fig. 10.

tin blocks. The beginning of this process is shown in figure 7. The type of stippled nucleus shown in figure 7 is characteristic of reticular cells regardless of their location. Free histiocytes also show this same type of nucleus even when they are derived from lymphocytes, as is often seen in inflammation of the loose connective tissue, as shown by Kolouch⁴³ (1939) in his figure 7b.

In imprints it is sometimes difficult to distinguish cells of the epithelial reticulum from those of mesenchymatous origin. The epithelial cells may round up and become free and there may be considerable clumping of chromatin. Usually the sharp nuclear groove or the pale translucent cytoplasm will serve to identify them as epithelial cells. However, where the cells are crowded between lymphocytes it may be impossible to classify them, especially when the mesenchymatous cells are undifferentiated and do not have the histiocytic type of cytoplasm seen in figure 7. In sections the difficulty is, of course, still greater.

Pinner,³⁸ who studied imprints of human thymus, does not mention the presence of any mesenchymatous cells. He did see epithelial cells with very leptochromatic nuclei, some of which had nucleoli. They were not described or illustrated in detail.

In the sections the mesenchymatous tissue often can be identified in some areas under the capsule and around the blood vessels which penetrate the cortex and medulla. When stained with azocarmine blue connective tissue fibers are seen to be most numerous in the medulla around the blood vessels but not entirely confined to the immediate neighborhood of the vessels. Some very thin fibers radiate for some distance from the vessels into the parenchyme, and some thin fibers penetrate

FIG. 4. Promyelocyte of mast leukocyte. The nucleus is similar to the one of fig. 1. Same imprint as figs. 1-3.

FIGS. 5 and 6. Epithelial reticulum cells from imprint. Note nuclear groove in fig. 5 and clumping of chromatin in fig. 6. The cytoplasm is characteristic and unlike that of the mesenchymatous cell of fig. 7. Same imprint as figs. 1-4.

FIG. 7. Imprint of cell from mesenchymatous reticulum. Newborn. Compare nucleus and cytoplasm with the epithelial cells of figs. 5 and 6. Note characteristic stippled nucleus and azurophilic granules in cytoplasm of fig. 7.

FIGS. 8 and 9. From imprint of newborn. FIG. 8. Lymphoblast showing very diffuse distribution of chromatin. In fig. 9 there is some clumping of chromatin and some stippling suggesting origin of this cell from mesenchyme.

FIG. 10. Section, young normal adult. Development of heterophils from mesenchymatous reticulum under capsule. Nucleus of upper granulocyte similar to nucleus of mesenchyme. Cytoplasm of mesenchyme cell not shown because it is unstained until granules begin to develop. The lower granulocyte shows that chromatin increases as the cytoplasm fills with granules.

FIGS. 11 and 12. Section, young normal adult. Hemocytoblastic myelocytes in septum. A slight amount of basophilic cytoplasm is still present.

FIG. 13. Section, young adult. Heterophil myelocyte in cortex.

FIGS. 14 and 15. Imprint, young adult. Lymphocytic heterophil promyelocyte and myelocyte with nuclei of small lymphocytes. Compare these nuclei with those of figs. 1, 2, and 4.

FIG. 16. Imprint, young adult. Heterophil metamyelocyte which seems to have developed from a cell like 15.

FIG. 17. Section. Eosinophil myelocyte with nucleus of small lymphocyte. This cell was one of a group of 5 similar cells in interlobular connective tissue. Eosinophils of this type and transitions between them and the bilobed form occur in the medulla. All the eosinophils of the rabbit thymus seem to develop from small lymphocytes. FIGS. 14 and 15 prove that heterophils also may develop from small lymphocytes.

the cortex from the surrounding connective tissue Strandberg³³ (1918) illustrated the distribution of these fibers which stain black with the Bielschowsky technic. They also have been described by others, so the details will not be given here. On account of the black staining with Bielschowsky it may be assumed that the thinner ones are related to reticular fibers and that some of the cells that produce them are reticular cells similar to the one illustrated in figure 7.

In sections the cytoplasm of these cells is almost colorless while they are in the inactive state. Their nuclei are round or elliptical. They contain little chromatin, but more and in coarser particles than is true of the epithelial nuclei. They do not have nucleoli. One of these nuclei is shown on the right of the 2 granulocytes of figure 10. The nuclear membrane is thicker than that of the epithelial nuclei. The cytoplasm was not stained. That cells of this type are mesenchymatous in origin is proved by the fact that some of them develop to granulocytes as illustrated in this figure. This will be described in detail later. A similar transformation of cells from the epithelial reticulum was not seen.

LYMPHOCYTES

The lymphocytes of the imprints are of the small, medium-sized and large types seen in imprints of rabbit lymph nodes. However, the nodes have some lymphocytes that are much larger than any encountered in the thymus imprints. The cytoplasm of these cells is usually smooth, homogeneous except for a few small vacuoles, and very basophilic. The nuclei are often immature in the sense that they show some characteristics of the nuclei of the reticular cells from which they are derived. These large cells and the medium-sized lymphocytes have more cytoplasm than is seen about the nuclei of the lymphocytes of the thymus, and the nodes have many more extremely basophilic cells of all types. Extremely basophilic cells are present in the thymus, but on account of the narrow rim of cytoplasm they are not very conspicuous. The nodes also contain many more immature lymphocytes than are present in the thymus. A detailed description of the lymphocytes of the lymph nodes and their regeneration will be found in the paper by Sundberg and Downey¹¹ (1942).

Small lymphocytes with very dark pachychromatic nuclei are the most numerous. They have so little cytoplasm that often it cannot be seen. The chromatin blocks are very dense and stain very dark blue which is almost black. Slightly less numerous are larger small lymphocytes with about the same nuclear structure but with chromatin less dense and staining violet rather than blue black.

Komocki⁴⁴ (1930) described and illustrated the dense nuclei of the small lymphocytes of the thymus. He believed that the smallest cells have no cytoplasm. Pollicard, Dustin and Marcus were quoted as supporting this opinion. He believed that the nuclei of the smallest lymphocytes of lymph nodes have a different structure and that they always are surrounded by cytoplasm. He agreed with Schridde that the nuclei of the small thymocytes are more loosely constructed than are those from the corresponding cells of the nodes. His illustrations of the small thymocyte nuclei are accurate but the figures of lymphocyte nuclei from the lymph of lymph nodes do not in any way resemble the nuclei of lymphocytes of either sections or

imprints of nodes Pappenheimer¹³ (1910) also believed that most of the small thymocytes have no cytoplasm that can be detected in smears, in which respect they differ from lymphocytes of lymph node smears. The thymocytes were thought to be epithelial elements.

It is true that most of the small thymocytes have very dark checker-board nuclei with sharply demarcated chromatin blocks separated by rather broad pale interspaces. Many of these nuclei are suggestive of the type seen in small plasma cells. Similar cells occur in lymph nodes of the same animals but they are not as numerous and their chromatin blocks usually are not as darkly stained. Naked nuclei similar to those of the thymus also occur in the nodes. Lymphocytes that are slightly larger than the smallest ones usually have cytoplasm in both nodes and thymus.

The writer concludes that every type of lymphocyte of the thymus can be duplicated in the nodes. However, certain types predominate in each of these organs, as has been shown in the preceding discussion.

Next in number in the thymus are medium and small large lymphocytes, usually with the nuclear structure of mature lymphocytes. Cells corresponding to the largest lymphocytes of the nodes do not occur. The cytoplasm of these thymus cells forms a narrow band about the nucleus, it is basophilic but usually not as dense and homogeneous as in the nodes. It usually has a light area at one side of the nucleus. Lymphocytes with abundant cytoplasm are scarce.

In sections narrow-bodied large lymphocytes are scattered among the small and medium ones of the cortex. There are very few large or medium-sized ones in the medulla. The largest ones with the most abundant cytoplasm tend to collect under the condensed connective tissue at the surface of the lobules. Here they approach in size the large lymphocytes of the nodes, although the nodes have some lymphocytes larger than any that occur in the thymus. Blood vessels of the medulla sometimes are surrounded by a dense collar of small and medium lymphocytes, a condition which seems to be more frequent during regeneration after radiation.

In the thymus imprints there is a fair number of large lymphocytes with very immature nuclei. In some of these cells it is diffusely distributed in the form of a delicate network or fine stippling without any clumping of chromatin. One such cell is shown in figure 8. Cells of this type are sufficiently immature to be called lymphoblasts. They resemble the lymphocytes of acute leukemia more than they do the immature reticular lymphocytes of the rabbit nodes. These blast cells are not numerous. Cells like the one of figure 9, in which there is some clumping of chromatin, are more numerous. The nucleus of this cell has some characteristics suggesting origin of the cell from a mesenchymatous reticular cell with a nucleus similar to that of figure 7. There is some clumping of chromatin but there is also some coarse stippling of the chromatin like that of figure 7. Some transitional forms between 7 and 9 could be found but they were not nearly as numerous as in lymph nodes. Illustrations of these transitional stages in lymph nodes are to be found in the papers of Downey and Stasney² (1936) and Sundberg and Downey (1942).

The presence of these transitional stages suggests that there is some development of lymphocytes from mesenchymatous reticulum in the thymus of normal animals. In the sections of normal animals it was impossible to see this line of development. However, during regeneration after irradiation of the thymus, as seen in sections stained with methyl green and pyronin, development of lymphocytes from the fixed tissue seems to be increased. This is probably the best stain that can be used for study of this process. The transition from fixed cells to free lymphoid cells was noted in several places at the periphery of the lobules near the capsule, and in the medulla close to the larger blood vessels. Downey and Weidenreich⁴⁵ (1912) published descriptions and colored illustrations of the development of lymphocytes from reticulum in sections of lymph nodes stained with methyl green and pyronin. The process is similar to what was seen in the irradiated thymus.

From the character of the intermediate cells of the imprints it seems clear that the fixed cells involved in this process are not of epithelial origin as some authors have assumed. Hartmann,⁷ better than any other author, has given an explanation of the presence of mesenchymatous tissue in portions of the cortex and in the medulla in the neighborhood of blood vessels. The mesenchyme which penetrates the organ in early embryonic stages is undoubtedly the fixed tissue which is capable of forming lymphocytes under certain conditions. Hartmann believed this but she was unable to demonstrate it with the methods she used.

The presence in the imprints of reticular lymphocytes similar to those of the nodes can be explained by the activity of the mesenchymatous tissue in the production of lymphocytes. However, this does not account for the immature lymphocytes of the "blast" type similar to those of lymphatic leukemia. Naegeli⁶⁵ believed that the lymphoblasts were not "blasts" but lymphocytes which were about to divide by mitosis or had just completed a division. This might be an explanation for the presence of such cells in the thymus but it does not account for their absence in lymph nodes. Mitoses were not very numerous in the normal thymus material used in this study. Their number was increased during regeneration following irradiation and the "blast" cells also seemed to be more numerous. The lymphoblasts do not seem to be an intermediate stage in the development of lymphocytes from the mesenchymatous reticulum. However, the thymus is not very favorable material for study of this question because the lymphoblasts are so few in number. The development of similar cells from the reticulum has been seen in human lymphatic leukemia by Fineman⁴⁶ (1922) and by Stasney and Downey⁴⁷ (1935).

GRANULOCYTES

As noted in the introduction, many investigators have seen myelocytes in the normal animal and human thymus. Some, like Hart,²⁴ thought they resulted from special conditions and so were not to be interpreted as a sign of hematopoiesis. Others believed they were formed in the connective tissue surrounding the thymus or were brought in by the blood. Pappenheimer^{13, 14} interpreted the eosinophil myelocytes as specifically differentiated epithelial elements which might have a secretory function. Hartmann⁷ could not find eosinophil myelocytes containing

only a few granules so concluded they were developed outside the thymus, while the heterophils were of local origin. Weidenreich⁷ and Weill¹⁰ are among the few who have studied the granulocytes in sufficient detail to trace their origin and transformation to mature leukocytes.

In the imprints there are two types of granulocytes in the heterophil series, viz., a type similar to those of the bone marrow (figs. 1-3), and the lymphocytic type (figs. 14-16) described by Weidenreich,⁷ Weill¹⁰ and Tuve.¹¹ In the youngest promyelocytes of the bone marrow type granules are not basophilic as they often are in the marrow. The basophil myelocytes (mast myelocytes) that were seen (fig. 4) were of the bone marrow type and were similar to the cells of the heterophil series (polymorphonuclears) except for the color and size of the granules. Eosinophil myelocytes and leukocytes were not numerous in the imprints. The nuclei of the myelocytes were of the small lymphocyte type, as shown in figure 17 which, however, is from a section. Imprinting does not change the morphology of these cells to any great extent.

The cells illustrated in figures 1-4 were compared to similar cells in excellent rabbit bone marrow smears loaned by Dr. Dorothy Sundberg of this Department. The lymphocytic type of myelocyte (figs. 14-16) was not seen in the marrow but cells comparable to those of figures 1-3 were numerous. However, there were some differences in structural details between the two series. The heterophil myelocytes of the thymus (figs. 1, 2) tend to spread out more and assume more irregular outlines than is true of the corresponding marrow myelocytes. This probably is due to difference in the character of the tissues. Owing to the thin spreading of the cytoplasm the granules of the thymus cells appear larger than those of the marrow.

In many of the marrow heterophil myelocytes some of the granules are basophilic, or of intermediate tints between basophilic and acidophilic. In the thymus the granules are always bright red. The only basophilic granules seen were in the mast leukocytes and their myelocytes (fig. 4). The coarse, dark 'myeloid azure' granules of irregular shape and size which are present in many of the marrow promyelocytes were not seen in the thymus imprints.

Nuclear structures of the myelocytes from the two tissues were quite similar. The nuclear pattern of the earliest promyelocytes is quite diffuse. It becomes coarser as the cells mature, as seen in figures 1-3. The nucleus of figure 1 shows some chromatin blocks which are not as dense as those of the more mature cells, and it also shows some stippling of the chromatin. In the marrow some of the promyelocytes have a more leptochromatic myeloblastic type of nucleus than those of the thymus. This may be only an apparent difference due to the greater number of myelocytes in the marrow which facilitates the finding of the various developmental stages.

The lymphocytic type of heterophil myelocyte seen in the imprints and illustrated in figures 14-16 was not seen in the marrow. The granules are identical to those of the marrow type of cell (figs. 1-3) but the nuclei are quite different, and the cytoplasm never shows more than a trace of basophilia. The nuclei are identical to those of small or medium lymphocytes. Their chromatin is in dense

blocks separated by clear interspaces and it stained very dark blue (fig 15) or violet as in figure 14. This difference in color probably is due to variations in the degree of spreading of the cells and their nuclei. The nucleus may be in the center of the cell but usually it is eccentric (figs 14, 15). A cell of this type with a central nucleus as seen in section is shown in figure 17.

In the marrow type of promyelocyte the cytoplasm is quite basophilic when the first granules appear. In the lymphocytic type the small lymphocytes develop a medium or wide cell body which becomes almost colorless. The first granules appear as very small pink specks in this colorless cytoplasm. A few of these cells with the nuclei of small lymphocytes (figs 14, 15) have a slightly basophilic area with few granules and a colorless area in which most of the granules are concentrated (fig 14). Cells of this type are not very numerous. That they complete their development is indicated by cell 16 which seems to be a metamyelocyte of this series. Several pseudoeosinophils with this type of nucleus, and transitional stages between this and the lobulated nucleus of the mature heterophil were found in the imprints.

In the sections most of the heterophil (polymorphonuclear) myelocytes are of the hemocytoblastic type of figures 11-13. Their nuclei are identical to those of the large basophilic lymphocytes of the sections. Their nuclear membrane is thick, the chromatin blocks are coarse, and there is good staining of the karyoplasm. Remnants of basophilic cytoplasm are often present (figs 11, 12), and in the younger promyelocytes it is obvious that the granules develop in a basophilic cytoplasm. A few heterophil myelocytes with dark, compact nuclei corresponding to those of figures 14 and 15 of the imprints were also seen in the sections.

All transitional stages in their development from large basophilic lymphocytes to mature cells can be found. Development of granules does not begin until the lymphocytes have acquired more than the usual amount of basophilic cytoplasm. Cells that are in compact groups are often in the same stage of development, thus, there may be several metamyelocytes in one group and only myelocytes in a neighboring group.

The distribution of these cells is quite irregular, they are numerous in some lobules, particularly the smaller ones that project for some distance into the surrounding connective tissue. Other lobules contain none. They are most numerous in the outer portion of the cortex close to the capsule, but they can also be located in any part of the organ. They are either scattered or in compact groups, and may be numerous in the medulla in the neighborhood of large blood vessels and connective tissue strands.

Another type of pseudoeosinophil myelocyte which usually occurs in groups of 2 or 3 cells immediately under the capsule is seen occasionally. Two such cells are shown in figure 10. Their nuclear membranes are thinner and the nuclei are paler than those of the hemocytoblastic type due to the lighter staining of the karyoplasm and the smaller and more diffusely distributed chromatin granules. The cytoplasm of the younger promyelocytes with few granules is only slightly basophilic, as seen in the upper cell of figure 10. The basophilia increases as the cells acquire more granules (lower cell of fig 10).

These cells develop from the stroma under the capsule. This reticular stroma is probably of mesenchymatous origin. Its nuclei have slightly thicker membranes, more chromatin, and absence of nucleoli to distinguish them from the nuclei of the epithelial reticulum. One such nucleus is shown on the right of figure 10. The cytoplasm could be seen but was practically colorless so has not been included in the figure. The nucleus of the upper myelocyte is identical to this nucleus, although somewhat smaller. The nucleus of the lower myelocyte has more chromatin and slightly darker karyoplasm, but it is not the lymphocytic type of nucleus of figures 11-13. It is possible that such a cell may eventually resemble the lymphocytic type. This point could not be settled because there are so few myelocytes developing from the fixed tissue. Some cells similar to the upper one of figure 10 were seen in the medulla where there may be much mesenchymatous tissue. It is logical to assume that they also have originated from mesenchymatous reticulum.

The rabbit is an animal that has few eosinophil leukocytes in its blood, marrow and thymus. While the total number in the thymus seems to be small they may be numerous in the medulla of some lobules. Their development in rabbit marrow from myeloblasts was described by Ringden⁴⁸ (1921) who showed marked changes in size and staining reaction of the granules as they matured. These changes in staining reaction of the granules were not seen in the imprints or sections of the thymus. The granules are larger and not as bright red as the pseudo-eosinophil granules and they are more refractile. They are often spindle shaped in the sections. Only a few of the mononuclear eosinophils had cytoplasm that was not completely filled with granules, which sometimes were a little smaller than those of the more mature cells.

Small and medium lymphocytes with dark checker-board nuclei seem to be the progenitors of all the eosinophils which are developed in the thymus and of a few of the marrow eosinophils. When the nucleus becomes bilobed the chromatin pattern remains essentially that of the small lymphocyte, although there may be some condensation of chromatin to form the cart-wheel type of nucleus. Tuve⁴⁸ and Weill⁴⁹ described two types of eosinophil myelocytes in human thymus, those with large leptochromatic nuclei and those with the nuclei of small lymphocytes. Only the latter type could be found in the rabbit.

Mononuclear eosinophils like the one of figure 17 often occur in groups in the interlobular connective tissue and in the septa. The cell of figure 17 is one of a group of five similar cells. Because of the number of these cells in the group, and because similar cells were seen in the imprints, one cannot assume that the nucleus is merely a section through one lobe of a bilobed nucleus, as was claimed by Schridde⁵⁰ for similar cells. Single cells of the same type are found occasionally in the medulla, and in some portions of the medulla, near large vessels and connective tissue strands, they and mature eosinophils with bilobed nuclei are quite numerous.

Mature mast leukocytes (basophils) with lobulated nuclei and a few of their promyelocytes and myelocytes were seen in the imprints of the thymus. They could not be identified in the sections, probably because the rabbit mast granules are very soluble in water. One of the promyelocytes is illustrated in figure 4. The granules have a violet or purple color with May-Giemsa staining and they vary somewhat

in size and shape. The nucleus of cell 4 is typical of the other basophil myelocytes that were seen. Its structure is identical to that of the bone marrow myelocytes whose origin could be traced to the myeloblasts. In the marrow smears examined the cells are not spread as thin as the one of figure 4, which probably accounts for the smaller size and darker staining of the granules of the marrow cells. Tissue basophils are very scarce in the rabbit and none was seen in the thymus of this animal.

The origin of some of the granulocytes of the thymus is not clear, and comparison of granulocytes of sections with those of the imprints is sometimes difficult. The cells of figures 1 to 3 seem to belong to one series. If one saw only cells 2 and 3 he would be inclined to believe that they were derived from lymphocytes on account of their nuclear structure. Cell 1 has a more immature nucleus with some stippling of the chromatin and some rather pale chromatin blocks which are composed of small chromatin granules. A nucleus of this type could have originated from a reticular nucleus, like that of figure 7, or from the nuclei of immature lymphocytes (figs 8, 9) which in turn may have been derived from the mesenchymatous reticulum. Cells 2 and 3 show that the nucleus acquires a coarser structure as the cells mature. This corresponds to the maturation of similar cells in the marrow and so does not necessarily mean that the cells have been derived from lymphocytes.

In myeloid metaplasia lymphocytes may change the structure of their nuclei to the type that is characteristic of the myeloblast before the cells develop granules. This dedifferentiation of the cells was noted especially by Dominici⁵¹ (1921 and earlier) and by Maximow² (1923). Dominici⁵¹ studied experimental myeloid metaplasia of the spleen and noted that some of the lymphocytes passed through a 'myeloid' stage during their evolution to the granulocyte while others did not. In the myeloid type of evolution the lymphocytes assume the character of myeloblasts with pale nuclei and little chromatin. In the lymphatic type of evolution lymphocytes of any type acquire granules without any further changes in nucleus and cytoplasm. In both cases the cells enlarge before producing granules, but in the myeloid type the nucleus enlarges more than the cytoplasm, so that the cytoplasm becomes relatively narrow and very basophilic. The lymphatic type of evolution is the more common one in the normal animal.

Maximow² (1923) saw myeloid metaplasia in cultures of rabbit lymph node to which cell free bone marrow extract had been added. All of the granulocytes developed from lymphocytes. In some instances the lymphocytes acquired large pale nuclei before developing granules, in others the lymphocytes were practically unchanged when they developed their granules. These observations are identical to those of Dominici⁵¹ in the mammalian spleen.

The dedifferentiation of lymphocytes which may occur before they develop granules makes it difficult to determine in all cases the origin of cells such as those illustrated in figures 1 and 4, especially in the thymus in which the myeloid transformation is not very active in the normal state.

Figures 14 and 15 illustrate another type of heterophil myelocyte seen especially

well in the imprints. Their nuclei have the structure of the small or medium lymphocyte, the intermediate stages in their development from lymphocytes were seen and have been described. In the sections most of the heterophils, like those of figures 11 to 13, are derived from large basophilic lymphocytes. It is possible, however, that cells 12 and 13 of the sections correspond to cells 14 and 15 of an imprint, although there seems to be too much condensed chromatin in cell 15 for the nucleus of a large lymphocyte.

The heterophils of figure 10 which have originated from the fixed mesenchymatous reticulum have nuclei which suggest that these cells correspond to cells of figures 1 and 2 of the imprints. In the imprints the mesenchymatous tissue has nuclei similar to the one of figure 7, in sections they appear as in the right-hand nucleus of figure 10.

REGENERATION OF LYMPHOCYTES AFTER IRRADIATION

From the character of some of the immature lymphocytes in the normal thymus one would suspect that there was some development of lymphocytes from the mesenchymatous tissue. However, all the transitional stages could not be traced in either sections or imprints. Several fields were located similar to the one shown in figure 10 in which granulocytes were developing from the fixed mesenchymatous tissue, but a similar origin for lymphocytes was not seen in the normal animal. This proves that regeneration of lymphocytes in the normal thymus is homoplastic, although it seems likely that a few are derived from the mesenchymatous portion of the stroma.

The picture is very different during the active phase of regeneration following irradiation. In this material many clear cut instances were seen of the development of lymphocytes from the mesenchymatous reticulum. Sections of thymus fixed in Helly's fluid, stained with methyl green and pyronin, and dehydrated with dioxan were especially good for this problem.

The animal used for detailed study was 4 or 5 months old. It was irradiated with a dosage of 500 r u and killed six days later. Thanks for this are due Dr. Harry W. Mixer of our Department of Radiology. Only the region of the thymus was irradiated. The dosage was probably sufficient to eliminate most of the lymphocytes from the organ.

Sections showed that recovery was not complete and that regeneration of lymphocytes was still in active progress. Mitoses were numerous. Although this was a late stage of regeneration the material was very favorable for study of the local origin of some of the lymphocytes.

The imprints from this animal contained many more large lymphocytes with immature nuclei, similar to those of figures 8 and 9, than were observed in the normal animal of this same age or in the thymuses of the newborn animals. Many of the nuclei were of the blast type, a few suggested origin from nuclei of mesenchymatous reticulum. The increased number of lymphoblasts might be accounted for by the numerous mitoses.

In the sections the boundary between cortex and medulla was not very sharp.

and often could not be determined. The cortex of most lobules was very narrow and its outer portion was very dense with closely packed lymphocytes, many of which were of the large variety. Mitoses were especially numerous in this region, and it was here that transitional stages between fixed tissue cells and lymphocytes were most numerous. The intermediate stages were similar to those of figure 10 except that the lymphocytes did not develop granules. Sections of this same material stained with Dominici showed that no new myelocytes were being formed and that those present were degenerating. Comparison with normal material leads to the conclusion that exposure to x-rays reduces or suppresses the local production of granulocytes.

Not all of the fixed tissue of the subcapsular region is of mesenchymatous origin, and it is only in a few limited areas that one can see the development of lymphocytes from the fixed tissue the characteristics of which have already been described. Islands of epithelial reticulum show no signs of activity, and this is also true of the compressed epithelium between the numerous lymphocytes of the peripheral cortex.

The lymphocytes originating from the mesenchyme are mostly large and they soon develop very basophilic cytoplasm. Their nuclei may still have the structure of the mesenchymatous nuclei and have very little chromatin. The cell outline usually is quite irregular but tends to become more rounded as the cytoplasm increases in amount and density.

Small and medium lymphocytes which have been formed in the outer portion of the cortex are crowded towards the medulla in dense strands between the radially arranged blood vessels. In the outer portions of the medulla of some lobules these strands may spread out to form irregularly shaped masses of densely packed lymphocytes. Similar dense groups of small lymphocytes may also occur deep in the medulla and in the cortex. They may also form dense collars about some of the blood vessels. This distribution of lymphocytes was also noted by Christensen and Griffith⁶² during accidental involution and early regeneration in rats.

Lymph vessels which usually accompany the larger blood vessels are often packed solidly with small and medium lymphocytes. Rudberg²⁵ thought this meant that during regeneration many of the lymphocytes immigrated through the lymph vessels, possibly from neighboring mediastinal lymph nodes which regenerate faster than the thymus. Both he and Hart²⁴ stated that the number of mitoses would not account for the rapid production of lymphocytes. Rudberg, although he worked with many x-rayed animals, could not see any evidence for migration of lymphocytes from the lymph vessels to the surrounding thymus tissue, and this is also true of the material being described in the present study.

The development of lymphocytes from the fixed tissue also occurs in the medulla in regions containing abundant connective tissue, large blood vessels, and often Hassall's corpuscles. Here it is again evident that the epithelial tissue which forms the corpuscles of Hassall is in no way associated with the production of lymphocytes.

The relative number of large lymphocytes is not as great in the medulla as in the

peripheral cortex. The lymphocytes developing from the fixed tissue are mostly of medium size and they originate from smaller mesenchymatous cells, with smaller nuclei than those of the cortex.

The other irradiated rabbit was an old animal in which the thymus was in an advanced stage of involution. The region of the thymus was exposed for a dosage of 400 r u and the animal was killed 8 days later.

The regeneration of lymphocytes is not as extensive as in the younger animal though the time interval between irradiation and death was two days longer.

There is marked hyperplasia of the epithelium which forms wide marginal bands in some places and large islands in others. The latter usually extend to the surface but may be central. These epithelial marginal bands and islands which form during the involution of the thymus were described in detail by Bienert (1923).⁵³

Most of the lymphocytes are concentrated in dense masses which usually have a central location but may be more peripheral and extend to the outer margin of the long narrow organ. It is difficult to see any reticulum in these regions. Epithelium of the islands and marginal bands forms a dense nucleated mass without cell outlines.

There are a few scattered lymphocytes and small groups of them in the epithelium. It was impossible to detect any mesenchyme associated with the epithelium which could give rise to lymphocytes. Large blood vessels are surrounded by connective tissue. Development of lymphocytes from this tissue could not be detected. A few lymph vessels are filled with lymphocytes, and this may be the chief source of the new lymphocytes, as there is no evidence for their formation from local fixed tissue in this animal.

Rudberg²⁵ states that after intense radiation which destroys all the lymphocytes the first ones to reappear enter the central portion of the organ where they proliferate and are later distributed to the cortex. Conditions in this animal seem to support Rudberg's conclusion. It is possible that in the older animals the mesenchymatous tissue, if present, is no longer capable of producing lymphocytes. More extensive material would be required to settle this point. In the young irradiated animal there is good evidence for the active production of lymphocytes in the cortex by mitosis and by heteroplastic development from the mesenchymatous reticulum.

Irradiation does not cause myeloid metaplasia of the thymus as does accidental involution from infections as described by Ssyssojew²⁶ in the thymus of children. No myelocytes were seen in the thymus of the younger irradiated animal, and only one small group of heterophil myelocytes was located in the older animal. Two myelocytes of hematogenous mast cells with large nuclei were seen, and tissue mast cells with small lymphocytic nuclei were fairly numerous in the older rabbit. A few plasma cells and plasma mast cells were also seen. There were no tissue mast cells in the thymus of the younger animal.

There were many cells which appeared to be macrophages in the sections of the older irradiated animal. They contained flakey, granular material which stained pale blue or green with the toluidin blue of Dominici's stain and light pink or

yellow with hematoxylin and eosin. The nuclei were eccentric, and in general appearance the cells were similar to the macrophages of subcutaneous tissue after colloidal dye injection. The included material resembles the endogenous granular substance derived from mitochondria described and illustrated by Tschassownikow³⁶ in fixed and free reticular cells of cultures of rabbit thymus. He found the epithelial cells of the cultures to be only slightly phagocytic. The granular cells of my preparations did not contain intact lymphocytes or their nuclei.

Some of the nuclei of the granular cells were of the histiocytic or lymphocytic type, but many had nuclei similar to those of the epithelial cells, including even the spherical nucleoli and nuclear grooves. The nuclear membrane often had many wrinkles. Some of the fixed epithelial cells also contained the same granular substance. The macrophages (?), therefore, seem to be of multiple origin, from lymphocytes, from mesenchymatous reticulum, and from the epithelial reticulum. It is very likely, however, that the technique employed did not permit distinction between true macrophages and epithelial cells. Tschassonikow³⁶ (1927) could not make the distinction in sections of rabbit thymus, but when he added lithium carmine to his cultures he observed the migration of dye-storing macrophages from the explant. The epithelium of his cultures did not store the dye.

The epithelial origin of macrophages of the thymus was claimed by many authors, among whom may be mentioned Rudberg,²⁵ Pappenheimer,¹³⁻¹⁴ Hart,²⁴ Wassén,⁵⁴ Ssyssojew,²⁶ Wituschinski,²⁷ and Marine.²⁸

Popoff (1926,²² 1928²³) never saw any macrophages or dye-storing cells developing from the epithelium of cultures and transplants. He derived all the carmine cells from embryonic mesenchyme about the blood vessels. He did not see an intimate mixing of mesenchymatous and epithelial tissues, but believed that the perivascular connective tissue would assume embryonic characters where it came in contact with epithelium. This is contrary to Wassen⁵⁴ (1915) who did not see macrophages growing out from the perivascular tissue of cultures of frog thymus, but did see their development from epithelium. The epithelium does not form macrophages or phagocytize degenerating lymphocytes according to Christensen and Griffith⁵² who obtained rapid involution in rats fed choline-deficient diets.

Tschassonikow,³⁶ from his work with cultures, concluded that the reticulum is composed of connective tissue elements and epithelium so intimately blended that they cannot be distinguished except when conditions are unusual, as during involution and in cultures, when the elements may separate and each differentiate in its own particular direction.

Wituschinski²⁷ (1926) claimed that histiocytes and macrophages which gather about a foreign body introduced in the thymus are derived from adventitial and other connective tissue cells, and from cells of the endodermal reticulum. He also claimed that hemocytoblasts which resemble large lymphocytes are derived from the endodermal reticulum under these conditions. The numerous granulocytes which develop around the foreign body he derived from the hemocytoblasts and adventitial cells of neighboring capillaries. He did not believe that lymphocytes could be derived from the epithelial reticulum.

In the material studied by the writer nothing was seen which would indicate origin of hemocytoblasts or other lymphoid cells from the epithelial reticulum. However, the material does show that the epithelial cells may become free rounded cells, some of which assume the form of unicellular Hassall's corpuscles, while others transform to macrophages, or at least to cells which resemble them very closely.

HUMAN THYMUS

Some human material became available during the course of this investigation. It was provided by Dr. Robert W. Collett, who performed the autopsies on infants and children who died in Minneapolis hospitals. The imprints made by Dr. Collett were studied by the writer. Sections were not available at the time this study was made. All of the material shows some postmortem change and was not good enough for detailed study of lymphocyte nuclei. However, it could be seen that the lymphocytes were practically identical to those of the rabbit except that the cytoplasm of the larger cells was not as basophilic. It was noted that the largest lymphocytes did not equal the largest ones of human lymph nodes, and that the thymocytes usually had less cytoplasm than the lymphocytes of lymph nodes.

There were some lymphocytes with leptochromatic nuclei but because of the postmortem changes one could not be certain that they were true 'blast' forms. Cells from the mesenchymatous reticulum, similar to figure 7 from rabbit, could not be identified. Cells from the epithelial reticulum, however, were quite numerous in some cases, especially in a 2 year old male who died of influenza meningitis, in a 10 weeks premature that lived 21 days, and in a $5\frac{1}{2}$ months aborted fetus which lived for 3 hours.

Several groups of 4 to 8 attached epithelial cells were seen, they were most numerous in the premature infant. Most of the epithelial cells, very numerous in the 2 year old child, occurred as single round, irregular or elongated cells. The round cells generally had smooth surfaces, while the margins of the elongated or irregular cells were often serrated or spiked. The nuclei were elliptical in the groups of attached cells and round in most of the free cells.

The nuclear membrane of all the epithelial cells was very thin. Many of these cells had 1 or 2 pale blue spherical nucleoli. In the largest epithelial cells the nuclei were very pale and had little chromatin which was widely dispersed in the form of fine strands and granules. The nuclei of all of the smaller cells had about the same structure, they were darker due to condensation of chromatin in dense short rods and irregular small masses with a considerable amount of pale pink parachromatin between them. The cytoplasm was opaque and nearly homogeneous. It was colored dark gray which often had a pale pink cast with May-Giemsa staining. In some cells it contained some blue flakes which appeared to be similar to the material included in the macrophage-like cells of the older irradiated rabbit. This substance was not abundant in any of the human cells, nuclei were not eccentric, and the cells did not resemble macrophages as they did in the rabbit.

The epithelial cells resist postmortem changes much better than the lymphocytes,

for all showed perfect preservation. Their nuclei and cytoplasm are so characteristic and specific that there was never any difficulty in identifying them. Only a few of these cells had the nuclear grooves that seemed rather characteristic of the rabbit epithelial cells. Many nucleoli were seen in the imprints, but in the rabbit they were seen only in the sections. The nuclei of the human cells are coarser and darker than those of the rabbit. The cytoplasm shows about the same structure and staining reaction in both.

All three types of myelocytes were seen in the human material. They were most numerous in the fetus and least numerous in the 2 year old child that died of meningitis. Most of the eosinophil myelocytes were of the bone marrow type and many had both basophilic and acidophilic granules in the same cell. This difference in staining reaction was also seen in some of the neutrophil myelocytes. These variations in staining were not seen in the rabbit thymus but were noted in the marrow. A few human eosinophils had small, dark lymphocytic nuclei. There were no basophilic granules in these cells. Most of the eosinophils of the rabbit were of this type.

Some macrophages with lymphocytic nuclei were seen in the thymus of the premature infant, and in a stillborn that died $1\frac{1}{2}$ hours before birth from toxemia. Some material that seems to have been phagocytized was included in epithelial cells of the latter case.

Although the human material was obtained at autopsy done several hours after death much of it was sufficiently well preserved to show great similarity between the human and rabbit thymus. There are some differences in details, as in the minute structure of the epithelial cells, the presence of basophilic granules in many of the human eosinophil and neutrophil thymic myelocytes, and the absence from the human thymus of lymphocytic neutrophil myelocytes similar to the pseudo-eosinophils of figures 14 and 15 from the rabbit.

Whether the human thymus also has immature lymphocytes of the 'blast' type could not be answered from this material. There is no explanation for the absence of mesenchymatous elements like the one illustrated in figure 7. Study of more favorable material will be necessary to determine whether the human reticulum contains less mesenchyme than that of the rabbit, or whether there is some other reason for its absence from the imprints.

DISCUSSION AND CONCLUSIONS

It has been shown that in the normal rabbit the thymus reticulum consists largely of epithelial elements. A small amount of mesenchymatous tissue is blended with this epithelial reticulum, but the cells of the two types of reticulum, which differ in embryological origin, retain characteristic morphological differences in the adult rabbit. The two types of reticular cells can be demonstrated in both sections and imprints. This is contrary to the opinion of others who, from the presence of fibers, from embryological studies, or tissue cultures of the thymus (Mietens,²¹ Jolly,²¹ Hartmann,⁷ Tschassonikow⁸⁶) concluded that the thymus stroma must include some mesenchymatous elements, although they could not see them in

histological preparations. The mesenchymatous elements are identical in structure and functional potencies to the reticulum of the other lymphoid organs. This tissue is not confined exclusively to perivascular regions, as Popoff²²⁻²³ seems to think it is, although it is more abundant in these locations, especially in the medulla.

The present study has shown that lymphocytes and granulocytes may develop from the mesenchymatous reticulum, although this type of heteroplastic development is not very active in the normal thymus and is difficult to demonstrate for lymphocytes. During active regeneration following irradiation of the thymus of a young animal many examples of the heteroplastic development of lymphocytes were seen. Some macrophages are also formed from free cells of this tissue.

The epithelium does not form lymphocytes or granulocytes. Some authors who believed that thymocytes (lymphocytes) were derived from the epithelium probably saw transitional stages between the mesenchymatous reticulum and lymphocytes. This is especially true of Prenant,¹⁹ who stated that mitosis in endodermal reticulum results in the formation of lymphoblasts with clear nuclei which divide and form lymphocytes.

Free rounded or irregular-shaped cells are liberated from the epithelium. These were especially numerous in some of the human material where they retained all their specific epithelial characteristics. In the irradiated older rabbit some of them assumed the form of unicellular Hassall's corpuscles, and others appeared to be macrophages which retained some of the nuclear characters of the epithelial cells.

Most students of the thymus problem agree with Rudberg,²⁵ Ssysojew,²⁶ Wituschinski,²⁷ Marine,²⁸ and others that the epithelium can form macrophages which phagocytize degenerating lymphocytes during pathologic involution and inflammation of the organ. However, Popoff²²⁻²³ and Tschassownikow,³⁶ working with transplants and cultures, concluded that dye-storing macrophages are derived from mesenchymatous elements only. It does not seem likely that epithelial macrophages which will phagocytize lymphocytes would not also store lithium carmine. It is generally agreed that the fixed epithelial cells, and the free ones which have not transformed to macrophages, will not store the dye.

The thymocytes are true lymphocytes of various sizes and nuclear structure corresponding to those of the lymph nodes. However, the rabbit thymus contains a few large lymphocytes with very immature nuclei (fig. 8) which resemble those of the rabbit myeloblast and lymphoblast of human lymphatic leukemia. According to Sundberg and Downey⁴¹ these are not present in the rabbit lymph nodes. The thymus contains only a few transitional stages between mesenchymatous reticulum and large lymphocytes. These are numerous in lymph nodes and they are usually large cells, larger than any that occur in the thymus. The absence of the largest lymphocytes from the thymus, therefore, seems due to reduced heteroplastic development of lymphocytes in the normal thymus as compared to lymph nodes. The small, medium and smaller large lymphocytes are identical to the corresponding forms of the nodes. The smallest lymphocytes with very dark nuclei with coarse chromatin blocks and little or no cytoplasm are more numerous in thymus than in node. Scanty cytoplasm is rather characteristic of the thymus lymphocytes.

which seems to support the view of Dustin¹⁰ that the nuclei are of chief importance for the function of the thymocytes

The thymic lymphocytes of different types can develop to granulocytes, and they do this in the normal rabbit and human thymus. They also differentiate to plasma cells and tissue mast cells. There were no basophilic granules in any of the heterophil or eosinophil myelocytes of the rabbit thymus. These dark granules are a conspicuous feature of these cells in the rabbit marrow, and they also occur in the corresponding cells of the imprints of human thymus, where most of the eosinophils are of the marrow type. In the rabbit thymus all the eosinophils seem to develop from small and medium lymphocytes with dark nuclei, and their granules are acidophilic when they first appear. Some of the rabbit granulocytes develop from the local mesenchyme (fig. 10) and this may be the origin of the marrow type of heterophil and basophil (figs. 1 and 4). Heterophils, like those of figures 14 and 15, could not be located in the rabbit marrow or the human thymus. They are fairly numerous in the rabbit thymus.

Study of regeneration of lymphocytes six days after irradiation of the thymus of a young adult rabbit showed that some of the lymphocytes are derived from the local mesenchyme under the capsule and in the medulla. The intermediate stages in the process could be traced. Many lymphocytes seem to enter the organ through the lymph vessels that accompany the larger blood vessels. Radiation seems to interfere with the development of myelocytes in the thymus, as none was found in the younger animal and only a few in the older one. Irradiation was also responsible for the production of many macrophage-like cells in the older animal. Many of these originated from the epithelium, but some had lymphocytic nuclei and others resembled the tissue type of macrophage. The fixed epithelium contained some included material that seemed to have been phagocytized. This gives some support to those who derive true macrophages from the thymic epithelium.

The development of lymphocytes from mesenchymatous tissue could not be detected in the older animal. This may be because regeneration of lymphocytes was not very active in this animal. Some tissue mast cells were seen in the thymus of this animal while in the younger animal the basophils were of the hematogenous type.

Mesenchymatous reticular cells could not be detected in imprints of human thymus. Cells of the epithelial reticulum are fairly numerous. They appear in attached groups or as single round or irregular-shaped cells. The nuclei of all these cells are of similar structure which is characteristic of the epithelial cells. Some of the nuclei have a surface groove and most have spherical nucleoli.

All three types of promyelocytes and myelocytes are present in the imprints of human thymus. They are similar to those of bone marrow with the exception of some of the eosinophils which develop from small lymphocytes.

The mature lymphocytes are similar to those of the rabbit, and, as in the rabbit, the largest lymphocytes of nodes do not seem to occur in the human thymus. The material was not adequate for determining whether the human thymus also has lymphoblasts or reticular lymphocytes.

SUMMARY

Thymocytes are genuine lymphocytes. The largest lymphocytes, of lymph nodes do not occur in the thymus, the smallest ones with pacychromatic nuclei and scanty cytoplasm are more numerous in the thymus. Some lymphoblasts similar to myeloblasts occur in the rabbit thymus.

All three types of granulocytes develop from lymphocytes and to some extent from the mesenchymatous reticulum in the rabbit. In the rabbit the heterophil and eosinophil granules are acidophilic when first formed, while in the human thymus many have a basophilic quota as in the marrow. The reticulum is largely of epithelial origin and retains its epithelial characteristics in cytoplasm and nucleus. In the rabbit some mesenchymatous tissue is blended with the reticulum and may give origin to lymphocytes and granulocytes. The epithelium may form macrophages but does not differentiate to lymphocytes and other types of cells. In imprints from the rabbit the epithelial cells usually can be distinguished from those of the mesenchymatous reticulum. During regeneration following irradiation the latter tissue can be seen to form some lymphocytes locally, other lymphocytes enter the organ through the lymph vessels.

Imprints stained with May-Grunwald and Giemsa are of great value for detailed cytology of the thymus and for determining cell relationships. Sections of thymus fixed in Helly's fluid, stained with methyl green and pyronin and dehydrated in dioxan are excellent for lymphocytes and the transitional stages resulting from their development from fixed mesenchymatous tissue during regeneration of the organ following exposure to x-rays.

ADDENDUM

Since this paper was written and sent to the editor an important paper on "Pure cultures of rabbit thymus epithelium," by R. G. Murray, has been published (*Am J Anat* 81: 369, 1947). By cutting away the main part of the explant and leaving only an epithelial outgrowth, Murray was able to obtain a pure culture of the epithelium. It was found that this epithelium grows like that from other sources. At times it grew like connective tissue, although mesenchymatous tissue could be excluded in this case. 'Pinocytosis' and possibly phagocytosis are characteristics not common to other epithelia. True macrophages, however, were not formed from the thymus epithelium. Evidence was not obtained for an epithelial origin of the rather numerous macrophages seen in the early and late cultures.

The thymocytes behaved like true lymphocytes and some of them developed to myelocytes with lymphocytic type of nucleus.

In two instances, mitoses of epithelial cells resulted in the formation of one daughter cell resembling a thymocyte, while the other one retained the epithelial character of the parent cell. This is the only evidence obtained from the cultures in favor of a possible origin of thymocytes from the epithelium.

In another recent paper, R. N. Baillif (*Anat Rec* 100: 16, 1948), concludes that in the involuting rat thymus, after injections of colloidal chlorazol black E and

mercuric sulfide, the epithelium differentiates directly to thymocytes and to macrophages which ingest the injected material. Most of the new lymphocytes produced during regeneration arise through transformation of epithelial cells.

It is possible that these conclusions can be explained by failure to distinguish between the epithelial and mesenchymatous portions of the thymus stroma.

THE EFFECT OF ENDOCRINOPATHIES ON THE BLOOD

By WILLIAM H. DAUGHADAY, M.D., ROBERT H. WILLIAMS, M.D.,
AND GENEVA A. DALAND, B.S.

WITH the rapid increase of knowledge of the many functions and interrelations of the endocrine glands, it is natural that their influences on the formed elements of the blood have received extensive study. The essential problem has been to determine just how much the elements of the blood are under direct endocrine regulation and how much they are affected by general metabolic alterations produced by hormones. Attempts to isolate a specific hemopoietic hormone or hormones have not been successful. Extracts of the anterior pituitary gland have been said to aid in the regulation of erythrocyte production¹ and certain steroids of the adrenal cortex are known to affect lymphoid tissue.² In this paper we propose to review some of the clinical and experimental evidence pertaining to this subject and to present some of our observations in an attempt to evaluate the importance of hormones in the regulation of blood production.

I. GONADS

A sex difference in the number of red blood cells and the concentration of hemoglobin has been well established for human adults. Exact figures vary but all authors agree that the values for the male are significantly higher than for the female. One authority³ states that the red blood cell count averages 4.8 million in females and 5.4 million in males. The concentration of hemoglobin shows a corresponding difference. This difference cannot be ascribed to blood loss in menstruation because a wide variety of mammals and even birds appear to have a well substantiated sex difference.

A mild anemia occurs after castration in the male hamster,⁴ rabbit,⁵ rat^{6,7} and chicken.⁸ The anemia is usually slightly hypochromic and microcytic. The administration of androgens, in general, has proved effective in restoring the red blood cell counts to normal or above normal. McCullagh and Jones⁹ have found a slight to moderate reduction in erythrocytes and hemoglobin in eunuchoid men. They showed that treatment with testosterone caused a rise in the red blood cell counts and hemoglobin, with cessation of therapy there was a reversal of these changes. An increase in the basal metabolic rate seemed to parallel the improvement in the blood picture. From these data they concluded that the sex difference in basal metabolic rate and in erythrocytes might be a related phenomenon.

Ovariectomy of rats causes a rise in the red blood cell count and hemoglobin to nearly the levels maintained by castrated males.⁶ The administration of estradiol to these animals yields values comparable to those of normal female animals. The chicken seems to respond somewhat differently in that the red blood cell count of

From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital, and the Department of Medicine, Harvard Medical School, Boston, Massachusetts.

ovariectomized hens is not significantly different from that in the hen. A depression or erythropoiesis follows large doses of estrogens in several species. A moderate to severe anemia has been produced in dogs with both natural and synthetic estrogens¹⁰⁻¹². The depression is not limited to the red cell series but a severe and sometimes fatal granulocytopenia or thrombocytopenia will occur on continued treatment. Monkeys seem to be much more tolerant of similar doses and show only a slight anemia.^{12, 13} Hematologic complications of estrogen therapy in humans seems to be rare.^{*}

There is not universal agreement as to sex differences in the number of platelets. A slightly lower average platelet count has been reported for women by Pohle.¹⁴ In 13 normal women it was found that a gradual decrease in platelets occurred during the fourteen days prior to menstruation which was followed by a rapid return to normal or increase after the onset of menstruation. Purpura hemorrhagica is found more frequently in females and cases of thrombocytopenic purpura have been described in which the purpuric episodes recurred only at the time of menstruation.¹⁵ These observations suggest that platelets are influenced by certain female sex hormones or perhaps by the menstrual toxin described by Smith and Smith.¹⁶

2. THYROID

Considerable clinical and experimental evidence indicates that the thyroid hormone has a definite influence on hematopoiesis. An anemia occurs with regularity in many laboratory animals following complete thyroidectomy. The changes which occur in the rat¹⁷ and rabbit^{18, 19} have received the most thorough study. The characteristic picture is a moderate anemia which is normochromic and slightly macrocytic. Gastric acidity in the rabbit is unchanged and megaloblasts do not occur in the bone marrow. A diminished ability to regenerate red cells and hemoglobin following a standardized hemorrhage has been demonstrated in thyroidectomized rats.²⁰ The defect was corrected by thyroxine, cobalt and testosterone, suggesting that the disturbance in blood regeneration is nonspecific.

Anemia is frequently observed in patients with myxedema. Emery²¹ attributed the first definite description of this feature of hypothyroidism to Charcot in 1881. This was seven years after Gull's original paper describing the disease. The report of the London Clinical Society on myxedema in 1888 added that allied with the fall in body temperature are changes in the blood. There is not only anemia due to loss of corpuscles, but the relative proportions of these constituents are also altered.²² Following these early observations, many other authors have confirmed and extended knowledge of this anemia. The importance of the recognition of this cause of anemia was emphasized in 1921 by Dr. Minot²³ in a clinic at which he presented two curable cases of anemia. The changes in the blood were summarized and the beneficial effects of treatment were described. In commenting on the etiology of the anemia he said: "The anemia in this case was apparently dependent upon a decreased formation of blood. This decreased activity of the marrow is

* One patient has been found to have repeated attacks of agranulocytic angina manifested on the first day of the menstrual cycle.²⁴

entirely consistent with the diminished activity of the other functions of the body."

Stern and Altschule²⁴ have described the blood changes in human beings under conditions which approach in simplicity the animal experiments referred to above. Their patients were subjected to total thyroidectomy for the relief of angina pectoris or congestive heart failure. An anemia of some degree was common and the onset of anemia seemed to coincide with the drop in the basal metabolic rate. There was a slight increase in mean cell volume and in color index. Some decrease in white blood cell counts occurred, but the differential counts remained unchanged.

Anemia in spontaneous myxedema has been found by Bomford²⁵ to be of three types. A slightly macrocytic variety of moderate severity commonly occurs. Similar to the anemia following thyroidectomy, it is characterized by a slight macrocytosis and increase in color index. It differs from pernicious anemia in that there is little poikilocytosis or anisocytosis of the erythrocytes and the bone marrow is hypoactive. Gastric function may or may not be normal. No reticulocyte response follows treatment with liver or iron, but the anemia slowly disappears on prolonged treatment with desiccated thyroid.

Some cases of myxedema may be associated with a hypochromic anemia of varying degree. Splenomegaly, a smooth tongue and changes in the nails are sometimes observed. The blood smear resembles iron-lack anemia with the exception that the cells tend to be larger. Achlorhydria is common but not invariable. A reticulocyte response to iron occurs, but complete recovery depends on both iron and thyroid.

Quite rarely Addisonian macrocytic anemia may be a complication of hypothyroidism. In such patients the signs and symptoms of pernicious anemia and combined system disease may be superimposed on the features of myxedema. The blood resembles pernicious anemia except that the color index may be even higher and the cells larger. Maximum improvement depends upon combined liver and thyroid treatment.

Bomford has concluded that the simple macrocytic type is the result of a decrease in size of the erythron as a physiologic compensation for the diminished need of the tissues for oxygen. The bone marrow undergoes hypoplasia, with shrinkage of its total volume. A marked reticulocytosis following treatment is not to be expected as compared to the anemias due to a maturation arrest. The slow return of the peripheral blood to normal values was explained by the gradual resumption of activity and cellularity in the bone marrow. The other two types of anemia are due to deficiencies of iron and liver extract factor apparently dependent on defective gastrointestinal function.

The simple slightly macrocytic anemia of myxedema occasionally is mistaken for pernicious anemia. However, little variation in size and shape of the red cells occurs in myxedema and the multilobed polymorphonuclear leukocytes and bone marrow changes associated with pernicious anemia are absent. The finding of normal gastric juice occurs in about one half of the cases of myxedema. The basal metabolic rate is of considerable aid in diagnosis because it is usually elevated in pernicious anemia. A yellow color of the skin may be common to both diseases, but

this pigment is bilirubin in pernicious anemia and excess carotene in myxedema. The most important differential point, however, is the presence or absence of an adequate reticulocyte response to liver extract therapy.

The frequency of anemia in spontaneous myxedema has been reported by Lerman and Means²⁶. Sixty per cent of 52 patients with myxedema had red blood cell counts of less than four million and 52 per cent had hemoglobin concentrations which were less than 70 per cent. Achlorhydria occurred in 53 per cent and was more frequently associated with anemia than was normal gastric acidity. These authors ascribed considerable etiologic importance to these changes in gastric secretion. The coexistence of myxedema and pernicious anemia seems to be more common than could be accounted for on the basis of probability. Means, Lerman and Castle²⁷ have described 5 such cases responding to liver extract.

Testosterone has been used in the treatment of anemia in myxedema by Glass²⁸. He reported the case of a 71 year old man with the classic features of myxedema. The red blood cell count was 2.8 with a color index of 1.1. Liver and iron had been given in adequate doses without increasing the number of erythrocytes. Four months of therapy with desiccated thyroid failed to correct the anemia. On the addition of testosterone and methyl testosterone to the therapeutic regime, the erythropoietic response was prompt and blood counts returned to normal in the course of a few months. An adequate hematologic response to desiccated thyroid might have eventually occurred in this patient, but the stimulating effect of testosterone on erythropoiesis cited above and the observed low excretion of 17-ketosteroids in myxedema provide a rational basis for such therapy. We have employed the combination of testosterone and desiccated thyroid in myxedema with apparent acceleration of blood regeneration, as illustrated by the following case.

Normocytic, slightly hypochromic anemia associated with myxedema with restoration of normal blood values after treatment with desiccated thyroid, testosterone propionate and ferrous sulfate

Case 1. M. V., a housewife, aged 47, of Irish parentage entered the Boston City Hospital in May 1945 complaining of weakness which appeared at the birth of her last child five years previously. The baby had been born at full term and the delivery was uncomplicated. Lactation was normal and menstrual periods returned at normal intervals following the cessation of lactation. She did note, however, increased fatigue and weakness. Somnolence and lethargy became troublesome. For one year she had noticed thinning of her hair and dryness of her skin. Bowel movements had continued to be regular. There had been no shortness of breath, numbness or tingling of the extremities, and no soreness of the tongue.

On physical examination the patient was a pale, somewhat poorly developed middle-aged female in no distress. The skin was cool and dry and the fingernails were brittle and spoon-shaped. The hair on the scalp was thin and dry and the axillary and pubic hair was sparse. The tongue was large but possessed normal papillae. The blood pressure was 101 mm. of Hg systolic and 75 diastolic and the pulse was 94. The heart and lungs were not abnormal. The liver and spleen could not be palpated. No abnormal neurologic signs were noted.

Laboratory examinations showed the following. Repeated urinalysis demonstrated only a small amount of albumin on occasions without other abnormality. The serum cholesterol was found to be 204 mg. per 100 cc. The prothrombin concentration was 50 per cent of normal. Carotenoids were demonstrated in the serum by a presumptive test. The basal metabolic rate was -36 per cent. An insulin tolerance test using 2.5 units of insulin, intravenously, did not reveal sensitivity or hypoglycemic unresponsiveness. A water test²⁹ and a sodium deprivation test³⁰ were normal, suggesting normal adrenal function. The sella turcica was normal by x-ray.

Examination of the blood showed a red cell count of 2.98 million, and the hemoglobin concentration

was 48 per cent * The white blood cell count was 7,200 and the differential count showed the following, polymorphonuclear neutrophils 64 per cent, band forms 6 per cent, eosinophils 1.5 per cent, basophils 0.5 per cent, small lymphocytes 15 per cent, large lymphocytes 3.5 per cent, monocytes 7.5 per cent and myelocytes 2.0 per cent. The platelets appeared normal.

The patient was given a diet of about 2,500 calories supplemented with vitamins in the form of Vegex, 90 cc per day, 2.5 mg of thiamin, 50 mg of ascorbic acid and 50 mg of nicotinic acid a day. Desiccated thyroid was begun soon after entry in a dose of 32 mg and was later increased to 96 mg. Ferrous sulfate was administered in a daily dose of 0.9 Gm for a week. Two cc of purified liver extract (Lilly) containing 30 USP units was given in a single dose by intramuscular injection. Five cc of crude liver extract (Wilson) was administered intramuscularly daily for five days. No significant increase in

FIG. 1. EFFECT OF THERAPY ON THE RED BLOOD CELL COUNT AND HEMOGLOBIN CONCENTRATION IN CASE 1.

reticulocytes was observed following any of the above therapies. The time relations of the various medications and the hematologic response are shown in figure 1.

At the time of the patient's discharge from the hospital, the red blood cell count was 2.9 million and the hemoglobin concentration was 56 per cent. She had noted improvement in strength and general well-being. The basal metabolic rate had risen to 18 per cent. She was followed at intervals in the outpatient clinic. From September 13 to October 27, 1945, she received a total of about 1400 mg of methyl testosterone in daily doses of 10-50 mg without improvement in her blood. In November 1945 she was readmitted for more intensive treatment. At this time it was noted that axillary hair was not present and that the spoon-shaped deformity of the nails was absent. The possibility of gastrointestinal bleeding as a cause for her refractory anemia was investigated. Repeated stool examinations were negative for occult blood. The basal metabolic rate was plus 10 per cent. In addition to desiccated thyroid, testosterone*

* One hundred per cent hemoglobin is equivalent to 15.6 Gm per 100 cc for all determinations from this laboratory.

propionate was administered three times a week in a dose of 25 mg by intramuscular injection. Ferrous sulfate, 0.75 Gm per day, was given for the last two weeks of her hospital stay. A progressive improvement of red blood cell count from 3.9 to 4.7 million occurred and the hemoglobin concentration increased from 65 per cent to 75 per cent. The same therapy was continued after discharge from the hospital and examination of the blood on January 28, 1944 showed normal values.

Comment This woman noted the onset of symptoms of hypometabolism following delivery. However, there was no abnormal bleeding or shock and the history of normal lactation and the reappearance of regular menstrual cycles indicates that if postpartum necrosis of the pituitary was the cause of her hypothyroidism, there was no panhypopituitarism. However, the laboratory data are consistent with primary thyroid myxedema. She presented a moderately severe normocytic, hypochromic anemia which did not respond to therapy with vitamins, liver extract and iron. The hemoglobin had risen slightly after five months of treatment with desiccated thyroid. The addition of testosterone propionate by intramuscular injection seemed to accelerate blood regeneration. The combination of iron, testosterone propionate and thyroid proved effective in restoring the blood to normal.

The changes in the blood in hyperthyroidism have received much study. The early clinicians believed that anemia was an important feature of the disease and in particular emphasized the association of hyperthyroidism with so-called 'chlorosis'. With improvement in methods for counting red blood cells and estimating hemoglobin and the systematic application of these methods to large groups of patients, it became apparent that some of the features of thyrotoxicosis which had suggested anemia had been misinterpreted. In the first comprehensive study of the blood in this disease by Kocher,³¹ the red blood cell count was generally normal and sometimes even above the levels then accepted as normal. Subsequent work by many authors has sustained this finding.

Changes which occur in the white cells have given rise to a great deal of study and speculation. After examining the blood of 106 patients with thyrotoxicosis, Kocher³¹ described in 1908 what he believed to be the pathognomonic blood picture in this disease. He emphasized the following features: a tendency toward leukopenia with a reduction mainly of polymorphonuclear neutrophils, both a relative and absolute increase in lymphocytes, a moderate increase in eosinophilic leukocytes. The changes in the white blood cells were claimed to be a reliable index of prognosis and the return to normal was believed to be a valuable indication of successful treatment.

Most subsequent investigators have been unable to confirm the significance of many of the features of the Kocher blood picture. Leukopenia was found to be usually slight and frequently absent. In general most of the reports have confirmed the tendency toward lymphocytosis, but the diagnostic usefulness of this change was lost when many other causes of lymphocytosis were recognized.

Recently Bistrom³² has carefully reinvestigated this problem. He made a comparative study of the morphology of the peripheral blood and bone marrow in patients with nontoxic goiters, toxic goiters and in control subjects admitted to the hospital for minor surgical procedures. The peripheral blood and bone marrow of patients with nontoxic goiters did not differ significantly from the control group.

In the group with thyrotoxicosis there were 33 patients. A moderate reduction in red cells and hemoglobin occurred in 10. The white blood cell counts were low or normal and a relative granulocytopenia and lymphocytosis were found on smear. The lymphocytic infiltration of the thyroid gland which was examined after surgical extirpation was correlated with the degree of lymphocytosis. Only minor changes suggesting greater immaturity of the predominant cells were found in aspirations of sternal marrow.

Treatment with iodine was followed by a return toward a more normal differential white blood cell count, but the three groups responded to an operation with about the same changes in the blood. The author concluded that the changes occurring in thyrotoxicosis were slight and inconstant and could not be of aid in diagnosis or in estimating prognosis. Other recent reports agree with this thesis.^{33, 34}

Probably associated with the lymphocytosis which may occur in thyrotoxicosis is the hyperplasia of lymphoid organs which occasionally is present. A generalized enlargement of the lymph nodes and spleen and a persistence of the thymus have been described.

The changes which occur in lymphocytes and lymphoid tissues have received many interpretations. It has been attributed to a constitutional abnormality not directly due to the thyroid.³⁵ A direct stimulating effect of the thyroid hormone on lymphoid tissue has been suggested.³⁶ Menkin³⁷ believed that the relative lymphocytosis in cases of exophthalmic goiter was due to sympathetic stimulation of lymphoid structures, particularly the spleen.

All authors do not agree that the lymphocytes are significantly increased. Hertz and Lerman,³⁸ using supravital staining technics, concluded that the most marked and characteristic finding in the blood of patients with exophthalmic goiter was a relative and absolute monocytosis. The lymphocytes were found to be normal in absolute numbers. The discrepancy of their observations as compared with the findings of others was attributed to the greater accuracy of the staining technic that they used.

In recent years the influence of adrenal hormones on lymphocytes and lymphoid tissue has been emphasized (*vide infra*). It is now evident that certain adrenal steroids oxygenated on the eleventh carbon atom cause a decrease in the number of circulating lymphocytes and a decrease in size of the thymus and lymph nodes. Selye³⁹ has described an apparent antagonism between the thyroid hormone and adrenal hormones in controlling the size of the thymus. No significant decrease in the weight of the thymus of rats occurred after thyroidectomy, suggesting that this hormone is not requisite for the persistence of the thymus. However the induction of stress in such rats by means of formaldehyde injections was followed by a severe and often fatal alarm reaction. The involution of lymphatic organs and thymus was much more marked than in intact animals. It appears, therefore, that animals which have been thyroidectomized are greatly sensitized to the action of adrenal hormones.

From these observations it would seem reasonable to suppose that the lymphocytosis and persistence of thymus which has been described in thyrotoxicosis

might be the expression of a relative deficiency of adrenal steroids. Some evidence that such a deficiency exists has been obtained in this laboratory.⁴⁰ Despite the severe stress imposed on patients with thyrotoxicosis, the excretion of 'cortin' as measured by a chemical method is frequently markedly subnormal. This observation has been interpreted tentatively as indicative of increased breakdown of hormone, although more studies are necessary to establish this as a fact.

3 THE ADRENAL CORTEX

Great advances have been made in the understanding of the physiology and chemistry of the adrenal cortex. The adrenal secretes several substances which have unrelated and even antagonistic actions. One of the most interesting phases of adrenal physiology has been the demonstration of the influence of the adrenal on lymphocytes and the release of antibodies.

In all laboratory animals adrenalectomy results in death after a short period if replacement of salt and/or hormones is not provided. Adrenalectomized rats show an increase in polymorphonuclear leukocytes and lymphocytes about twenty-four hours before death.⁴² An increase in the weight of the thymus and systemic lymph nodes has been reported in adrenalectomized rats maintained in good condition by means of the addition of sodium chloride to their drinking water.⁴² In cats surviving a relatively long time after operation there is a decrease in polymorphonuclear cells and an increase in lymphocytes.⁴³ Increases which have been reported in the red blood cell count and hemoglobin concentration are indications of the disturbed electrolyte and fluid metabolism which causes marked hemoconcentration.⁴⁴ If adrenalectomized cats and dogs are maintained in fair general condition by several different methods of treatment, the peripheral blood is essentially normal.

Adrenal insufficiency in human beings produces changes similar to those in experimental animals. During an adrenal crisis there is usually a slight increase in red blood cell count and hemoglobin and a relative lymphocytosis. Restoration of normal blood volume by the use of desoxycorticosterone and saline solution frequently reveals a mild underlying anemia. A relative lymphocytosis may persist even after treatment.⁴⁶

Polycythemia has been a frequent, but not a constant, finding in Cushing's syndrome.^{47, 48} Approximately one-half of the well authenticated cases have shown an elevation of the red blood cell count.⁴⁹ Gunther⁵⁰ has collected data on 7 patients with hyperadrenalcorticism with red counts in excess of six million. The abnormality is usually mild and associated mainly with rapid progress of the disease. In itself it does not seem to produce the complications which are observed in polycythemia vera. Many patients with Cushing's syndrome are suspected of having polycythemia in whom subsequent blood counts fail to confirm the clinical impression. A plethoric appearance of the cheeks is common and is due to atrophy and stretching of the skin which permits the transmission of the color of the underlying venous plexuses. Combined with the marked deposition of fat about the face and neck, the red cheeks constitute the pathognomonic facies described by Cushing.

White and Dougherty^{2 51} have studied the effects of adrenotrophic hormone and adrenal cortical steroids on red cells and hemoglobin. A single injection of either substance will cause a transitory increase in the red blood cell count, followed by a decrease to lower than pretreatment levels. The continued injection of adrenotrophic hormone resulted in a significant increase in red blood cell count and hemoglobin. The authors concluded that 'it is possible that repeated hormone injection eventually leads to a stimulated production of red cells in an effort to compensate for the diminution of erythrocyte count produced by a single dose of hormone'.

In a number of experimental conditions the size of the thymus varies inversely with the activity of the adrenal cortex. This has been most clearly demonstrated in the response of an animal to stress. Selye³⁹ has introduced the concept of the 'alarm' reaction as a phase in the general adaptation of the body to harmful stimuli. An increase in the size and activity of the adrenal cortex is a fundamental element in this process. One of the most striking and constant changes is the involution of the lymphatic organs. The loss of weight is most marked and rapid in the thymus. Here the characteristic cells of the parenchyma, the thymocytes, actually disintegrate and twenty-four hours after the onset of a severe alarm reaction only the debris of their chromatin is left lying partly free in the reticulum, partly in phagocytes which are engaged in removing it. The lymph nodes also show signs of involution but without any noticeable hyperplasia of the reticulum. The involution in them usually begins in the germ centers which may disappear almost completely. That the involution of the thymus is secondary to the adrenal cortical activity seems probable because no change occurs in adrenalectomized animals. The injection of certain adrenal steroids into intact animals or adrenalectomized animals, and the injection of adrenocorticotrophic hormone into intact or hypophysectomized, but not adrenalectomized, animals, will reproduce similar changes in lymphoid tissue and thymus.^{52 53}

Dougherty and White^{2 54} have confirmed and extended these observations by reporting a remarkable decrease in the circulating lymphocytes after the injection of adrenocorticotrophic hormone or cortical steroids into the mouse, rat, rabbit and dog. This phenomenon has been termed 'lympholysis'. Lympholysis in the mouse is particularly striking. Within an hour after the injection of adrenocorticotrophic hormone there occurs a definite fall in the circulating lymphocytes which reaches a maximum in six to nine hours. Recovery to normal takes place within twenty-four hours. Probably considerable variation in sensitivity of lymphocytes to lysis exists because in our laboratory⁵⁵ rats of the Sprague-Dawley strain have shown little lymphopenia after injection of aqueous adrenal cortical extract.

Minor changes in chemical structure have been shown to modify the action of various adrenal steroids on lymphocytes. 11-Desoxycorticosterone has been demonstrated to be without effect.² On the other hand Compound E (11-dehydro-17-hydroxy corticosterone) and other active steroids with an oxygen on the eleventh carbon atom possess this property.

The destruction of lymphoid tissue is believed to be the source of the increase in

serum beta and gamma globulins which follows injections of active hormones of the adrenal cortex. Direct analysis of lysed lymphoid tissue washed free of all blood serum has demonstrated proteins which are indistinguishable from serum beta and gamma globulins.⁵⁶ In immunized animals the lymphocyte contains antibodies which are liberated into the blood stream by the process of lympholysis.⁵⁷ Dougherty and White⁵⁴ believed that the above mechanism is the explanation for the anamnestic reaction which occurs in acute infection.

The effect of adrenal steroids on the lymphocytes of human beings has not been reported in any detail. Dougherty and White² reported observations on several patients with lymphocytic leukemia and also in control subjects. A suggestive drop in the lymphocytes was observed in some of the patients. Forsham et al.⁵⁸ observed the effects induced by synthetic 11-dehydrocorticosterone acetate on the lymphocytes. In thirteen experiments on patients with Addison's disease 20-60 mg. of the compound were given as a daily dose. No significant decrease in the lymphocytes was found. It was noted, however, that there was an increase in urinary uric acid excretion in comparison to creatinine. These data seem to suggest that a tissue rich in nucleoproteins was being broken down and it is therefore possible that there was significant 'lympholysis' which was not manifest in the circulating blood. Perera et al.⁵⁹ have used the same compound and found an inconstant decrease in the lymphocytes following administration to human beings. Recently Thorn's collaborators⁶⁰ have presented interesting observations on the effect of adrenocorticotrophic hormone on the blood picture of man. In normal subjects four hours after the administration of 25 mg. of adrenocorticotrophic hormone by intramuscular injection there was a 90 per cent increase in the absolute number of polymorphonuclear neutrophils, a 40 per cent decrease in lymphocytes and a 78 per cent decrease in eosinophils. Similar changes did not occur in patients with Addison's disease. However the administration of 20 mg. of 17-hydroxycorticosterone to such patients caused an increase of 129 per cent in the absolute number of polymorphonuclear neutrophils, a decrease of 53 per cent in the lymphocytes and a decrease of 76 per cent in the eosinophils.

In our experience little change in the relative or absolute number of lymphocytes follows the administration of adrenal cortical extract in doses of from 10 to 50 cc. to patients with adrenal insufficiency. Figure 2 shows the results which we have obtained on treating a patient with hypopituitarism for nine days. Both adrenal cortical extract (Upjohn) and lipoadrenal cortical extract (Upjohn) were given in doses which are in excess of those required to maintain patients with Addison's disease.

Because of the apparent failure of moderate doses of adrenal cortical extract to alter the blood picture, larger doses were administered. A patient with hypopituitarism secondary to a chromophobe adenoma was selected. Immunization against heat-killed typhoid bacilli was achieved by three injections of 0.1 cc. of a standard vaccine.* It is interesting that despite the small size of the immunizing

* This material was very kindly supplied by the Department of Public Health, Antitoxin and Vaccine Laboratory, of the Commonwealth of Massachusetts.

dose the patient noted marked local and systemic symptoms following each injection and that there was a satisfactory rise in antibody titer. Forty cc of adrenal cortical extract was given in two equal doses by intramuscular injection. Figure 3 shows the changes which occurred in the lymphocyte count, the anti-typhoid agglutination titer and the titer of anti-B isoagglutinin (the patient was blood group A). A brisk fall in the number of lymphocytes was noted after six hours with a return to normal after twenty-four hours. A rise in the anti-typhoid agglutination titer was noted at six hours, there was a decline by twenty-four hours and a return

EFFECT OF ADRENAL STEROIDS ON RELATIVE DIFFERENTIAL COUNT

FIG. 2. CHANGES IN DIFFERENTIAL WHITE BLOOD CELL COUNTS IN A PATIENT WITH SIMMONDS' DISEASE AFTER THE ADMINISTRATION OF ADRENAL CORTICAL EXTRACTS

Note the apparent drop in eosinophils with negligible changes in other cell element

to the former titer by six days. No significant change occurred in the anti-B isoagglutinin titer.

The experiment was repeated after the injection of 50 mg of testosterone propionate daily for three days and 25 mg for four days. Following this treatment the anti-typhoid titer seemed to decline. The changes which followed injection of adrenal cortical extract were similar to those observed in this patient prior to testosterone therapy.

We have concluded from these limited observations that the lowering of the lymphocyte counts with a rise in immune bodies, which has been observed in laboratory animals, can be reproduced in human beings, but that relatively large doses of adrenal cortical extract are required.

Other mechanisms of regulation of lymphocytes than pituitary-adrenal control must exist. This is evident from the study of adrenalectomized rats maintained on salt. Crafts¹⁷ found that such animals maintained a normal white count and differential count. De La Balze, Reifenshtein and Albright⁴⁶ reviewed their extensive experience with adrenal disorders in man and could not establish a significant increase in the absolute number of lymphocytes in patients with Addison's disease, although the relative number of lymphocytes was increased.

EFFECT OF ADRENAL CORTICAL EXTRACT ON LYMPHOCYTES AND ANTIBODIES

FIG. 3. NOTE THE LYMPHOPENIA AND INCREASE IN THE TITER OF ANTITYPHOID AGGLUTINATION FOLLOWING THE ADMINISTRATION OF ADRENAL CORTICAL EXTRACT.

4 THE PITUITARY GLAND

Discussion of the possible mechanisms by which this gland alters hematopoiesis has been reserved until last. It is well known that the anterior lobe of the pituitary gland controls the activity of the other endocrine glands and it could thereby aid in the regulation of formed elements in the blood. It is, therefore, evident that the anemia which is often observed following destruction of the anterior pituitary is a complicated phenomenon.

An anemia following hypophysectomy was first noted by Aschner⁶¹ in dogs in 1912. Later it was determined that rabbits⁶² and rats⁶³ respond to the operation in

a similar manner. Destruction of the pituitary in man frequently results in a moderate anemia.

The decrease in the red blood cell count and hemoglobin which occurs in the hypophysectomized rat, has received the most intensive study. In 1935 Stewart, Greep and Meyer⁶⁴ noted that hypophysectomized rats were anemic and that there was a decrease in the number of reticulocytes. A rise in reticulocytes occurred in normal rats exposed to reduced oxygen tension, but not in hypophysectomized ones. Increases in the red blood cell count and hemoglobin of the hypophysectomized rats occurred only if the stimulus of low oxygen tension was applied soon after operation. The reticulocyte response following substitution therapy parenterally has proved an unreliable criterion because reticulocytosis has been produced by many hormonal and nonhormonal agents.⁶⁵ In general, reticulocytosis has been unaccompanied by improvement in red blood cell count and hemoglobin concentration. The conclusion was reached that the alterations in the blood following hypophysectomy were due to general disturbances in metabolism rather than the absence of a specific hematopoietic hormone.

On the other hand, the existence of a specific pituitary hormone which stimulates blood formation has been postulated by Moechlig and Bates.⁶⁶ The polycythemia of Cushing's disease was attributed to an excessive production of this factor.

On the basis of the response of hypophysectomized rats to oral administration of preparations of anterior pituitary, Flaks, Himmel and Zlotnik^{1, 67} postulated the existence of an erythrogenic hormone. They claimed that the anemia of hypophysectomized rats was repaired and that polycythemia was produced by their hormone preparation in intact animals. It is difficult to accept this claim because of the impotency of known pituitary hormones when administered orally.

Beneficial effects on the anemia of hypophysectomized rats have followed treatment with several hormones, pituitary as well as non-pituitary. Vollmer and Gordon⁶⁸ and Vollmer, Gordon and Charipper⁶⁹ found that testosterone propionate increased the red blood cell count of hypophysectomized male and female rats. Estradiol, on the other hand, seemed to intensify the anemia. Pregnant mare's serum raised the red blood cell count of hypophysectomized male rats, but lowered the counts in hypophysectomized female rats. Thyroxine plus testosterone was moderately effective. Prolactin seemed to be inactive. Desoxycorticosterone produced no definite effect on the bone marrow.

Various types of replacement therapy have been investigated by Crafts.^{70, 71} In hypophysectomized female rats the anemia was found to be microcytic and hypochromic and accompanied by hypoplastic changes in the bone marrow. Iron or iron plus copper delayed slightly the onset of anemia. Injection of 0.01 mg. of thyroxine daily maintained a normal erythrocyte count, but did not prevent a decrease in hemoglobin concentration. Histologic examination revealed greater cellularity of the bone marrow and decreased infiltration by fat cells. This was interpreted as an indication of increased activity. The combination of thyroxine, iron and copper maintained a normal red cell count and seemed to increase the amount of hemoglobin. Hypophysectomized adult male rats developed a severe microcytic, hypochromic anemia with hypoplastic changes in the bone marrow. Testosterone

therapy prevented the decrease in the red blood cell count and restored the bone marrow to normal cellularity. Microcytosis and hypochromia were only partially corrected. Because the anemia following castration was much less marked than that following hypophysectomy, the author believed that the anemia in the latter condition was not a manifestation of decreased androgens, although androgens proved partially effective in preventing the experimentally induced anemia.

An anemia following destruction of the anterior lobe of the pituitary in man has been long recognized as a significant feature of the clinical syndrome called Simmonds' disease. Silver⁷² reviewed the literature in 1933 and observed that anemia is a constant finding. The hemoglobin averages 50 per cent, with a color index which is usually less than one. Leukopenia is common and an eosinophilia reaching 22 per cent may occur.

Snapper, Groen, Hunter and Witts⁷³ described 6 cases which they believed presented evidences of pituitary or gonadal deficiency plus an anemia. Case 2 of their series was a woman with pituitary necrosis following hemorrhage and shock at the time of delivery. A macrocytic anemia of 3.2 million red blood cells was present. Case 3 was a patient with hypopituitarism secondary to a chromophobe adenoma. There was a moderately severe macrocytic anemia, accompanied by gastric achylia and evidence of combined system disease. In the other cases hypogonadism was probably primary. The importance of achlorhydria and defective absorption was stressed as the immediate cause of anemia leading to deficiency of either iron or the hemopoietic principle of liver extract. Witts⁷⁴ later described two additional cases which he considered to be examples of hypopituitarism and which were associated with a macrocytic anemia responding to liver. He concluded: "The association of pernicious anemia with hyperthyroidism, with pregnancy and with pituitary disease, suggests that there is a hormonal element or mechanism which can lead to the degeneration of the cells which secrete intrinsic factor. We may consider the association of pernicious anemia with hypopituitarism as another example of the precocious senile changes to which the patient with pituitary disease is liable."

The effect of testosterone propionate on the anemia of hypopituitarism has been the subject of a recent report.⁷⁵ Two cases of hypopituitarism with anemia are described that responded to the combined administration of testosterone and liver. In one patient at least it is evident that no response occurred with liver extract alone. It was suggested that testosterone enabled the bone marrow to utilize the hematinic principle, which it previously had been unable to do.

Escamilla et al.⁷⁶ have reviewed 101 cases of Simmonds' disease, verified by post-mortem examination. Among this group the hemoglobin ranged from 10.2 per cent to 40 per cent, with an average of 65 per cent. Red blood cell counts ranged from 5.6 to 2.0, averaging 3.7 million. Eosinophilia was commonly observed, with 63 per cent as the average figure.

Sheehan^{77, 78} has emphasized the importance of serious hemorrhage and shock at the time of delivery as an etiologic factor producing necrosis of the anterior lobe of the pituitary. The lesion is a thrombotic infarction of variable extent, which later may reduce the anterior lobe to a nubbin of fibrous tissue. This group of

particularly valuable for an understanding of the anemia in Simmonds' disease because the time of onset can be fixed with some certainty and it occurs in young adult females who may live with hypopituitarism for many years. Quite frequently the blood deficit of the precipitating hemorrhage is incompletely restored. However, for the first five years it is not uncommon for these patients to maintain relatively normal red blood cell counts, but with a rather low hemoglobin concentration. During the second five year period there is a definite tendency for the red blood cell count to decrease to between 3 and 4 million, with some increase in the color index. The blood frequently remains at this level indefinitely. Occasionally there is a further decrease in the red blood cell count to a level of from 2 to 3 million with a color index of 0.95 to 1.25. These cases showing a severe anemia and a tendency toward macrocytosis seem to occur in patients with more profound evidences of deficient thyroid function and may be indistinguishable clinically from thyroid myxedema. Leukocytes usually number between 4 to 6 thousand, although leukopenia is common. The smear characteristically shows a relative lymphocytosis with a moderate eosinophilia in about two thirds of the cases.

The results of therapy on the blood in hypopituitarism have received scant attention in the literature. The use of anterior pituitary hormones is the rational approach to the problem, but has not proved successful. Extracts of the pituitary of high potency and purity have not been available. Because of their protein nature, pituitary extracts rapidly lose their effectiveness because of the development of antihormones. Also allergic manifestations, such as urticaria and local pain are common. Because of these disadvantages it has been more practical to use the hormones of the atrophic "end-organ" glands.^{79, 80} The combination of desiccated thyroid, desoxycorticosterone acetate and testosterone has provided a reasonably satisfactory method of treatment.

In this clinic the above therapy has been used with various modifications in the treatment of Simmonds' disease. Marked relief from many of the disabling symptoms of this disease has been obtained, but improvement in the blood findings has been inconstant. The following case (case 2) is reported in detail because this patient had been under observation for a period of nine years and during this period adequate trial with many therapeutic agents failed to correct an anemia. Case 3 is reported to show that improvement in the blood may follow hormone treatment without the addition of liver or iron. Hematologic data on 22 patients with hypopituitarism observed during the past six years are presented in table 1.

Pituitary fibrosis of unknown etiology associated with a moderately severe normocytic and normochromic anemia which failed to respond to liver, iron and hormone therapy

Case 2 F. S. (Details of this case have been reported elsewhere.^{79, 80}) A white housewife of American parentage, aged 38, entered the Boston City Hospital October 18, 1934 complaining of weakness and vomiting. Following an attack of influenza two years prior to entry, she had been told that she had anemia and low blood pressure. Recovery from this illness was protracted and incomplete and she continued to suffer from asthenia, fatigability, drowsiness and anorexia. A local physician prescribed ground raw liver which she took for a period of about six months without improvement in any of her complaints. She sought hospital care after two weeks of nausea and vomiting. Her past history revealed that she had given birth to a normal child about ten years previous to entry. A hysterectomy was performed some time after delivery for pelvic peritonitis. Unfortunately details of the delivery and operation are not available.

On physical examination she appeared to be an underdeveloped and poorly nourished woman. The skin was pale, smooth and had a yellowish, waxy texture. The tongue had normal papillae. The blood pressure was 92 mm of Hg systolic and 68 diastolic. A mass interpreted as the liver edge was felt on

TABLE I—*Hematologic Observations in Hypopituitarism*

All cases presented clinical and laboratory evidence indicating deficiency of two or more of the following hormones: gonadotropic, thyrotropic, adrenotropic and growth hormone.

† Diagnosis established at operation.

A high protein diet with vitamin B complex was given. In addition she received iron, liver and desiccated thyroid separately and in combination for intervals of several weeks without a reticulocyte response.

or improvement in her anemia (see figure 4) Removal of some badly infected teeth seemed to improve her general condition The patient was discharged from the hospital in April 1935

She was seen by Dr Juda Groen in September 1936 at the Boston City Hospital at which time she reported slight improvement in appetite and strength, although she had failed to take desiccated thyroid regularly Signs of myxedema were evident and the absence of axillary and pubic hair was recorded The blood findings were much the same as before

At this time the patient failed to return for further treatment and continued to live a restricted life at home Fatigue and somnolence became increasingly incapacitating until by 1941 she was almost bed ridden Anorexia became almost total and in November 1941 she had an episode of confusion and dis

FIG 4 CHANGES IN RED BLOOD CELL COUNT AND HEMOGLOBIN CONCENTRATION IN CASE 2

Data have been plotted as averages for ten day periods Note the apparent absence of response to many different forms of treatment

orientation and because of this she was sent to the Massachusetts Memorial Hospital She was found to be acutely dehydrated and in poor condition on admission Numerous petechiae were present over the right arm The blood pressure was recorded as 108 mm of Hg systolic and 78 diastolic After adequate repair of her dehydration it was evident that her anemia was practically identical to that observed seven years previously The red blood cell count was 3.78 million and the hemoglobin concentration was 65 per cent The white blood cell count on admission was 6,400, with 43 per cent lymphocytes present The platelets numbered 172,000 Aspiration of bone marrow was performed and the following cell distribution was found

No follicle stimulating hormone was found in the urine upon testing for 10 rat units per twenty-four hours. The patient excreted 0.2 mg. of 17-ketosteroids per twenty-four hours. An insulin tolerance test, using 0.05 units of insulin per kilogram of body weight, intravenously, demonstrated moderate hypoglycemic unresponsiveness. A water test²⁹ was positive, but a salt deprivation test³⁰ was negative. The basal metabolic rate was -23 per cent.

On January 9, treatment was begun with desiccated thyroid, 32 mg. daily, and this was progressively increased to 160 mg. daily. Two pellets of desoxycorticosterone acetate, 125 mg. each, and two pellets of testosterone, 150 mg. each, were implanted subcutaneously. The patient was much improved by this treatment as far as her general condition was concerned, but no improvement in her anemia occurred, and she was discharged from the hospital in May 1942.

In November 1943 she entered the Boston City Hospital for replenishment of her therapy. She was given ferrous sulfate by mouth and desoxycorticosterone acetate and testosterone propionate by intramuscular injection. Therapy with desiccated thyroid was continued. Unfortunately, after a month in the hospital she developed virus pneumonia and died after a brief stormy course.

At postmortem examination the pituitary was very small and fibrotic. Microscopic study showed only a few acidophilic, basophilic and chromophobe cells scattered in dense scar tissue. The thyroid gland was one half normal size and the acini were very atrophic. Extensive adrenal atrophy and fibrosis was found. Microscopic examination of the bone marrow was interpreted as showing less than normal erythropoiesis. There was no evidence of a defect in maturation. Cells of the granulocytic series appeared to be normal except for a questionable increase in the eosinophilic series. Megacaryocytes were of the usual number.

Comment. The etiology of the pituitary fibrosis in this case remains obscure. The onset of symptoms following influenza suggests that this may have been the etiologic factor. The anemia in this patient was normochromic and normocytic and remarkably constant in severity. It was unaffected by raw liver by mouth, liver by injection, iron in several forms and by hormonal replacement treatment.

Postpartum necrosis of the pituitary associated with a moderately severe normocytic and normochromic anemia with improvement after hormone therapy.

Case 3. H. O. N. (Details of this case have been reported elsewhere⁷⁹⁻⁸⁰) A housewife, aged 42, was admitted to the Boston City Hospital in May 1941 with the signs and symptoms of myxedema. Twelve years prior to entry she had had a severe hemorrhage due to a placenta previa. Following this episode menstruation never recurred and symptoms of hypometabolism were noted. She was treated by several local physicians for hypothyroidism and anemia but the details are not available. She took desiccated thyroid only at irregular intervals and at the time of entry the classic features of myxedema were present, with marked mental and physical retardation. However, her nutritional status was good. Pubic and axillary hair was absent. A hypotension of 90 mm. Hg systolic and 50 diastolic was present. The laboratory findings confirmed the diagnosis of Simmonds' disease. The basal metabolic rate was -43 per cent. Plasma protein bound iodine was less than 1 microgram per cent. Marked sensitivity and hypoglycemic unresponsiveness was demonstrated by an insulin tolerance test (0.04 units of insulin intravenously per kilogram of body weight). No follicle stimulating hormone was found in her urine when tested for 10 rat units per twenty-four hours. Free acid was not present in the gastric juice even after the administration of histamine.

Hematologic data. The red blood cell count was 3.45 million, the hemoglobin was 71 per cent and the hematocrit was 30 per cent. Calculation of the blood indices showed a mean corpuscular volume of 87 cu. microns, a mean corpuscular hemoglobin concentration of 37 per cent and a mean corpuscular hemoglobin of 32 micro-micrograms. Two-tenths of one per cent of all erythrocytes were reticulocytes. The white blood cell count was 2,100. The differential count was as follows: polymorphonuclear neutrophils 52 per cent, band forms 14 per cent, eosinophils 2 per cent, basophils 4.5 per cent, lymphocytes 19 per cent, young lymphocytes 1 per cent, monocytes 7.5 per cent.

The patient received several pituitary hormones without clinical or hematologic improvement. There was a decline of the red blood cell count and hemoglobin concentrations as shown in Figure 3. Replacement therapy with nonpituitary hormones was begun on December 29, 1941, with the admini-

tration of methyl testosterone, 30 mg a day by mouth, desiccated thyroid 30 mg a day by mouth and desoxycorticosterone acetate 2 mg a day by intramuscular injection. At a later date pellets of testosterone and desoxycorticosterone acetate were implanted subcutaneously. Details of therapy are indicated in figure 5.

There was a remarkable improvement in the patient's general condition on this therapy. Prior to treatment, the basal metabolic rate was -53 per cent and it rose to normal after treatment for 1 month. The myxedematous changes disappeared and there was a progressive improvement in her energy and strength. The red blood cell count and hemoglobin concentration on January 17, 1942 showed even lower values than previously. The mean corpuscular volume on this occasion was 111 cu microns. One month later the red blood cell count had increased to 4.05 million, with a decrease in the mean corpuscular volume to normal size, 83 cu microns, and 4.5 per cent of the erythrocytes were reticulated. On March

FIG. 5. CHANGES IN RED BLOOD CELL COUNT AND HEMOGLOBIN CONCENTRATION FOLLOWING ENDOCRINE THERAPY IN CASE 3.

20, 1942 the red blood cell count and hemoglobin had returned to normal levels. On follow up examination the improvement in the blood picture was largely sustained, despite the fact that additional pellets of testosterone could not be procured for replacement.

The patient re entered the Boston City Hospital in January 1944 with pneumonia and, in spite of treatment with sulfathiazole, adrenal cortical extract, desoxycorticosterone and testosterone propionate, she died four days after admission.

At postmortem examination the pituitary was found to be very small and appeared on microscopic examination to be composed largely of fibrous tissue, with rare nests of basophilic cells. Marked atrophy of the thyroid was present and no tissue recognizable as adrenals was found. On microscopic examination the vertebral marrow appeared hypoplastic. Red blood cell and white blood cell precursors were present and showed no evidence of a defect in maturation.

Comment The onset of symptoms in this woman following a severe hemorrhage complicating a placenta previa strongly suggests that the atrophy and fibrosis of the pituitary observed at autopsy was due to postpartum necrosis. A moderately severe normocytic anemia was present on admission and became more severe during the period of observation. The macrocytosis observed in January 1942 may have been related to an increase in the severity of her thyroid deficiency as manifested by a basal metabolic rate of -53 per cent in December 1941. On combined hormonal treatment the red blood cell count and hemoglobin concentration returned almost to normal in the course of about three months. It seems likely that testosterone propionate was the agent causing the improvement in the blood picture.

SUMMARY AND CONCLUSIONS

Evidence has been presented that the gonads, thyroid, adrenal cortex and pituitary glands have a definite influence on blood formation. The normal sex difference in erythrocyte levels in animals, and probably in man, can be obliterated by castration and restored by appropriate replacement therapy. Hypothyroidism results in a moderately severe anemia in animals. In the uncomplicated form, the anemia is slightly macrocytic and associated with a hypoplastic bone marrow. In clinical experience the anemia may be complicated by the secondary effects of achylia gastrica leading either to iron deficiency or to a deficiency in the anti-pernicious anemia factor. Hyperthyroidism causes some alterations in the white blood cells, but has little effect on the red blood cell series. Hyperactive states of the adrenal cortex may be associated with a mild polycythemia. Adrenal steroids also have a marked lymphocytic effect, causing the release of beta and gamma globulins from lymphoid tissue. A mechanism involving the anterior pituitary and adrenal seems to exist, controlling the release of antibodies under certain conditions. It is suggested that other mechanisms also exist which control the number of circulating lymphocytes.

Deficiency of the anterior pituitary secretions results in anemia in animals and man. The anemia in animals is usually microcytic and hypochromic and may respond to several types of replacement therapy. In man anemia develops slowly and is rarely severe. Moderate reductions in the red blood cell count occur and the color index varies. There is hypoplasia of the bone marrow. The anemia in man does not respond uniformly well to the therapy now available, but improvement often occurs with the replacement of 'end-organ' hormones.

The preponderance of evidence indicates that the regulation of blood formation is not primarily under hormonal control. The effects noted in various glandular disorders are due to alterations in metabolism produced in the bone marrow as well as all other body tissues.

OBSERVATIONS ON THE MECHANISM OF HEMOLYSIS IN PAROXYSMAL (COLD) HEMOGLOBINURIA

By A. A. SIEBENS, M.D., W. H. ZINKHAM, M.D., AND PHILIP F. WAGLEY, M.D.*

PAROXYSMAL (cold) hemoglobinuria is a condition observed usually in syphilitics and characterized by transient hemoglobinemia and hemoglobinuria following exposure to cold. Such episodes of hemolysis may be associated with fever, chills, headache, general malaise, abdominal cramps, nausea, vomiting, hives, and Raynaud's phenomena. The most common complaint is dark or bloody urine following exposure to cold.

As late as 1868 this condition had not been differentiated from the hemoglobinuria of malaria.¹ However, by the end of the nineteenth century all of the clinical features mentioned above were recognized and the condition established as a clinical entity.² From 1909 to 1929, occasional observations suggested that factors other than cold might activate this hemolytic system. For example, van den Bergh³ and Hannema and Rytma⁴ observed that carbon dioxide under specified conditions in vitro might affect the degree of hemolysis. Manneberg and Donath⁵ reported the same results but also observed that carbon dioxide caused hemolysis in normal human blood. Kumagai and Ito⁶ reported equivocal results. Although Mackenzie could not duplicate van den Bergh's results in vitro, he observed attacks of hemoglobinuria in a case following emotional disturbances without exposure to changes in temperature.⁷ Both van den Bergh and Mackenzie concluded that factors other than cold might activate this system.

Some observers state that serum complement must be present during the cold phase of the Donath-Landsteiner reaction for the hemolysin to be active.⁸⁻¹⁰ Other investigators have reported that complement need be present only during the warm phase.¹¹⁻¹² Mackenzie has stated that, although complement may not be essential for the first phase of the Donath-Landsteiner reaction, it is adsorbed during the chilling process when present.¹² In some of his experiments the hemolysin apparently was fixed on the erythrocyte in the absence of complement, but supplementary observations suggested that the presence of complement during chilling increased the degree of hemolysis occurring subsequently at body temperature. Differences in the thermolability have been reported¹¹ for the hemolysins studied in various cases.

In this communication, observations are reported in an attempt to re-evaluate several of these reported discrepancies. Two cases of paroxysmal (cold) hemoglobinuria were studied, as described briefly in the appendix of this report. The experiments are divided into two groups:

1. The first deals with the fixation of the hemolysin and complement on the

* Research Fellow of the American College of Physicians.

erythrocytes This group of experiments shows that the hemolysin and at least one component of complement are fixed to the red cells in the cold, and that some thermostable component of complement must be present in the warm phase of the Donath-Landsteiner reaction for the hemolysin to be effective

2 The second demonstrates that although carbon dioxide, under specified conditions in vitro affected the hemolytic system in the serum of one patient, it failed to do so in the serum from another patient Furthermore, certain substances prevented the hemolytic activity in the serum from one case, but failed to do so in the serum from a second case The effectiveness of these inhibitors did not depend on prevention of fixation of hemolysin on the red cell in the cold phase of the Donath-Landsteiner reaction

MATERIALS AND METHODS

Group O erythrocytes were washed three times and resuspended in normal saline in a concentration of 5 per cent by volume Guinea pig serum diluted 1 to 5 with normal saline was employed as complement The complement titer* was recorded as the highest final dilution of serum causing hemolysis in a system containing 0.1 cc aliquots of a 1.5 per cent suspension of sheep cells sensitized with rabbit amboceptor to which serial dilutions of 0.1 cc of serum were added Serum was obtained from blood drawn from the patients into syringes and tubes warmed to body temperature Standard technics were employed for determinations of carbon dioxide, cyanide, and sulfanilamide¹³⁻¹⁵ Hydrogen ion determinations were made with a glass electrode employing a Beckman meter The Donath-Landsteiner test was done according to a standard technic¹⁶ The titer of cold hemolysin in the serum was determined by employing serially diluted serum, and a constant amount of complement, in the Donath-Landsteiner test The anti human serum rabbit serum was prepared and used as described by Coombs et al¹⁷

EXPERIMENTAL RESULTS

Group I *Experiments on the fixation of hemolysin and complement during the Donath-Landsteiner reaction*

The object of the following experiment was to determine the phase of the Donath-Landsteiner reaction during which complement and hemolysin were adsorbed by the erythrocyte

A Experiment on fixation of hemolysin and complement in the cold

Washed normal Group O red blood cells were packed in 0.5 cc aliquots in four tubes (see table 1) To two of the tubes (Nos 1 and 3) 2 cc of serum from Case 1 were added To the other two tubes (Nos 2 and 4) 2 cc of serum from Case 2 were added Then 0.5 cc of saline was added to all tubes Tubes 1 and 2 were kept at 27 C for one hour with frequent mixing Tubes 3 and 4 were chilled at 2 C for thirty minutes and then centrifuged after being packed with ice in large centrifuge metal cups Tubes 1 and 2 were centrifuged at 27 C The clear supernatant was removed quickly from all four tubes

Results and conclusions The titer of complement and hemolysin in the supernatant removed from the cell-serum mixtures kept at 27 C were both high However, both hemolysin and complement activity disappeared from the serum previously chilled at 2 C in the presence of cells Presumably, hemolysin and one or more components

* The term complement activity is used to indicate the hemolytic reaction of serum with sensitized sheep cells as described above Since all components of complement are necessary for the hemolytic reaction with sensitized sheep cells, the absence of complement activity is interpreted as indicating the lack of one or more of these components

of complement were adsorbed by the red blood cells at the lower temperature but not at the higher one. Such adsorption of hemolysin and complement from the serum of Case 2 caused no significant alteration in the electrophoretic pattern of the serum.¹⁸

The question then arose as to what would occur if hemolysin and complement were separated and chilled separately in the presence of red blood cells.

B Experiment on complement and hemolysin activity in the cold phase of the Donath-Landsteiner reaction

Serum from Case 2* was heated at 63 C for three minutes. Two-tenths of a cubic centimeter of this serum caused no hemolysis of 0.2 cc of a 1:5 per cent suspension of sensitized sheep cells (see tube 1 of table 2). The remainder of the serum was divided into 0.5 cc aliquots and, as shown in table 2, was placed in tubes 3 and 5. Five-tenths of a cc of unheated serum were placed in two other tubes (see tubes 2

TABLE 1—*Adsorption of Hemolysin and Complement*

Test tube	Case 1 serum	Case 2 serum	Control packed R B C	Normal saline	Hemolysin in* supernatant	Complement in† supernatant
	cc	cc	cc	cc	titer	titer
1	2.0		0.5	0.5	1/4	1/128
2		2.0	0.5	0.5	1/32	1/32
3	2.0		0.5	0.5	0	0
4		2.0	0.5	0.5	0	0

Procedure: Test tubes 1 and 2 left at room temperature (27 C) for 1 hour, then centrifuged at 27 C, and supernatant tested for hemolysin and complement. Test tubes 3 and 4 chilled at 2 C for 30 mins with frequent stirring, then centrifuged in cold, and supernatant tested for hemolysin and complement.

* As determined by Donath-Landsteiner tests on serially diluted supernatant.

† As determined by adding 0.1 cc 1:5% sensitized sheep R B C to 0.1 cc portions of serially diluted supernatant.

and 4 of table 2.) To the four tubes were added 0.2 cc of a 5 per cent suspension of washed normal Group O red blood cells. One-tenth cc of normal saline was added to all four tubes. To tubes 2 and 3 were added 0.2 cc of a 1:5 dilution of guinea pig serum. All four tubes were then chilled at 2 C for ten minutes. After the chilling, 0.2 cc of a 1:5 dilution of guinea pig serum were added to tubes 4 and 5. All tubes were then incubated at 37 C for 1 hour.

Results and conclusions As shown in table 2, hemolysis did not occur if cells were chilled in heat-inactivated serum unless complement was added *before* chilling. Adding complement to previously heated serum *after* the chilling phase of the Donath-Landsteiner reaction did not cause hemolysis. Apparently, complement had to be present during the cold phase of the reaction to cause hemolysis. This was also suggested by rechilling tube 5 of table 2. Such subsequent rechilling and re-warming resulted in almost complete hemolysis. This substantiated the conclusion

* The hemolysin in the serum of Case 1 was found to be more thermolabile than complement when heated at 56 C. Attempts to separate the thermolabile hemolysin and the complement by adsorption on other antigen-antibody precipitates failed since both were adsorbed simultaneously. In contrast, the hemolysin in the serum of Case 2 was thermostable, thus allowing inactivation of the complement without destroying the hemolysin.

that hemolysin was present but was active only when chilled in the presence of complement

These conclusions were substantiated by another technic. The serum of Case 2 and guinea pig serum were heat inactivated at 57 C for thirty minutes. These sera and unheated sera were combined as shown in table 2-A and chilled with cells at 3 C for ten minutes, then incubated at 37 C for thirty minutes. Small aliquots of cells chilled in the presence of the various combinations of sera shown in table 2-A

TABLE 2 — *Effect of Complement on the Cold Phase of the Donath-Landsteiner Reaction*

Test tube	Case 2 serum	Case 2 serum heated at 63 C-3 min	Cont R B C	Compl added before chilling	Compl added after chilling	Norm saline	Sensitized sheep R B C (1.5%)	Hemolysis
1	cc	cc	cc	cc	cc	cc	cc	0
2	0.5	0.2	0.2	0.2		0.1	0.2	++++
3		0.5	0.2	0.2		0.1		+++
4	0.5		0.2		0.2	0.1		++++
5		0.5	0.2		0.2	0.1		0

Procedure: All tubes chilled at 2 C for 10 minutes, then incubated at 37 C for one hour

TABLE 2 a — *Demonstration of Adsorption of the Hemolysin on Red Cells by the Agglutination of such Cells (in a Saline Suspension) following the Addition of Anti-human Serum Rabbit Serum*

Test tube	Case 2 serum	Case 2 serum heated at 57 C 30 min	Complement	Complement heated at 57° C 30 min	R B C (5 per cent suspension)	Hemolysis*	Coomb's serum agglutination†
1	cc	cc	cc	cc	cc		
2	0.5		0.2		0.3	2+	2+
3		0.5	0.2		0.3	tr	1+
4	0.5	0.5		0.2	0.3	0	0
				0.2	0.3	1+	2+

* Hemolysis as determined after chilling the suspension 10 minutes and incubating at 37 C for 1 hour

† Coomb's test was performed by incubating 0.2 cc of a cell suspension with 0.2 cc Coomb's serum and expressing the agglutination as 4+ to 0 on microscopic examination

were removed prior to incubation at 37 C and resuspended in several cc of saline. By resuspending the cells in saline immediately after chilling, they could be kept indefinitely without lysis (see tubes 3 and 6 of table 3). Two-tenths of a cubic centimeter of such suspensions of red cells were then incubated at 37 C for one hour with Coomb's serum.¹⁷

Hemolysis occurred only when the serum of Case 2 or that of the guinea pig had not been previously heated. Heating both sera prior to the chilling phase of the Donath-Landsteiner test prevented subsequent hemolysis. Cells, after being chilled in the presence of both hemolysin and intact complement and resuspended in saline, were agglutinated by anti-human serum rabbit serum.¹⁷

This agglutinability of the cells occurred following their chilling in the presence of the hemolysin when guinea pig serum furnished the only complement, it did not occur when both the complement in the patient's and guinea pig sera had been previously heat inactivated. These observations suggested the hemolysin was adsorbed only in the presence of intact complement, whether the latter was furnished by the human serum or guinea pig serum.

Since both the hemolysin and at least the thermolabile components of complement were required in the cold to sensitize red cells, the role of complement during the warm phase of the Donath-Landsteiner reaction was studied. Therefore, the following experiment was performed.

TABLE 3—*Effect of Complement on the Warm Phase of the Donath-Landsteiner Reaction*

Test tube	Sensitized* cont R B C (5%)		Compl	Compl heated at 63 C -3 min	Normal saline	Hemolysis
	Case 1	Case 2				
	cc	cc	cc	cc	cc	
1	0.2		0.2			++++
2	0.2			0.2		0
3	0.2				0.2	0
4		0.2	0.2			++++
5		0.2		0.2		0
6		0.2			0.2	0

Procedure: Compl, heated compl, and normal saline added to sensitized cont R B C at room temperature (circum 27 C). All tubes then incubated at 37 C for one hour.

* Sensitized cont R B C prepared by chilling cont R B C for 15 mins at 2 C in presence of sera of case 1 and case 2. R B C then washed with normal saline and resuspended in 5% concentration.

C Experiment on complement and hemolysin activity in the warm phase of the Donath-Landsteiner reaction

Packed washed normal Group O red cells were chilled at 2 C for fifteen minutes in twice their volume of unheated serum from Case 1 or Case 2 (see table 3). Saline, chilled to 4 C, was then added and the cells washed while cold. They were then resuspended in normal saline in 5 per cent concentration and warmed to 27 C. Two tenths of a cubic centimeter of the suspension of red cells previously chilled in the serum of Case 1 were placed in three tubes (tubes 1, 2, and 3 of table 3) and equal aliquots of cells previously chilled in the serum of Case 2 were placed in three other tubes (tubes 4, 5, and 6). Two-tenths of a cubic centimeter of guinea pig serum diluted 1 to 5 were added to tubes 1 and 4, 0.2 cc of guinea pig serum diluted 1 to 5 with saline and inactivated by heating at 63 C for three minutes were added to tubes 2 and 5, and 0.2 cc of saline were added to tubes 3 and 6. All the tubes were then incubated at 37 C for one hour.

Results and conclusions Cells that were previously chilled in the presence of fresh serum from both cases, then washed and resuspended in saline, did not hemolyze on incubation unless intact complement was present also during the warm phase. Adding heat inactivated complement or more saline did not cause hemolysis. Presumably, red cells sensitized in the cold phase by hemolysin and complement could not be hemolyzed in the warm phase unless intact complement was present. Thus,

some thermolabile component of complement was required during the warm phase of the Donath-Landsteiner reaction

Group II Experiments with carbon dioxide and inhibitors of carbonic anhydrase

As previously reported,¹⁹ relatively high contents of carbon dioxide, under certain conditions in vitro, may cause hemolysis of cells suspended in the serum of some cases of paroxysmal (cold) hemoglobinuria. Other observers,^{6, 2} in similar experiments, have not obtained these results. In a previous communication,¹⁹ preliminary observations were made on the effect of carbon dioxide on the Donath-Landsteiner reaction of Case 1, as reported in more detail here. One possible interpretation for the discrepancy in the reports concerning the effect of carbon dioxide might be that there were possible differences in the temperatures at which the experiments were performed by different observers. For example, it had been reported¹⁹ that carbon dioxide caused complete hemolysis of Group O cells suspended in the patient's serum (Case 1) when the temperature was 27 C, but no hemolysis occurred at 37 C. It was conceivable, therefore, that exposure to relatively high temperatures had resulted in no hemolysis, whereas lower temperatures could have produced hemolysis. It had already been established that the hemolysin in the serum of various patients was activated at different temperatures.² Accordingly, there was a distinct possibility that the effect of carbon dioxide on the hemolytic system in the sera of various cases might appear at different temperatures. However, further observations suggested that a simple difference in temperature threshold was probably not the explanation for such discrepancies in the literature. For example, bubbling in carbon dioxide under oil at a temperature of 11 C caused no more hemolysis of cells suspended in the serum of Case 2 than allowing such suspensions to simply stand at the same temperature for the same length of time. Furthermore, cyanide and sulfanilamide, when employed as reported before,¹⁹ did not inhibit the hemolytic activity of the serum from Case 2. These results were in striking contrast to those observed in the study of Case 1.¹⁹ Accordingly, the effect of sulfanilamide and cyanide on the Donath-Landsteiner reaction was studied in more detail by using the serum from Case 1, as indicated in the following series of observations.

A Experiments on the phase of action of sodium sulfanilamide and cyanide on the Donath-Landsteiner reaction

Two-tenths of a cubic centimeter of a 5 per cent suspension of normal washed Group O red blood cells were placed in each of 6 tubes (see table 4). To tube 1 was added 0.1 cc. of normal saline, to tubes 2, 3, 5, and 6 were added 0.1 cc. of complement as guinea pig serum diluted 1 to 5 with saline. (As complement was already present in the serum of Case 1 [see table 1] the addition of more complement was actually unnecessary.) One-tenth of a cubic centimeter of 0.08 M solutions of sodium cyanide and sodium sulfanilamide were added to tubes 2 and 3, respectively. Five-tenths of a cubic centimeter of serum from Case 1 were placed in all tubes. All tubes were then chilled at 2 C for fifteen minutes. At the end of that time, 0.1 cc. of normal saline, 0.08 M sodium cyanide, and 0.08 M sodium sulfanilamide were added to tubes 4, 5, and 6, respectively. All tubes were then incubated at 37 C for one hour.

Results and conclusions Hemolysis occurred in all tubes except those chilled in the presence of sulfanilamide and cyanide. Adding sulfanilamide and cyanide after

the chilling phase did not prevent hemolysis. Apparently, therefore, cyanide and sulfanilamide had to be present during the chilling phase of the Donath-Landsteiner reaction in order to prevent hemolysis.

These observations raised the question of whether these substances prevented sensitization of red cells by the hemolysin or prevented the hemolysis of already sensitized cells. The following experiment was performed in the attempt to answer this question.

B Experiment on the effect of sodium sulfanilamide and cyanide on the union of hemolysin with red blood cells

Four-tenths of a cubic centimeter of a 5 per cent suspension of normal washed Group O cells were placed in each of 3 tubes (see table 5). Four-tenths of a cubic centimeter of complement in the form of guinea pig serum diluted with 1 to 5 with saline and 1.0 cc of serum from Case 1 were added. Two tenths of a cubic centimeter of normal saline, 0.08 M sodium cyanide, and 0.08 M sodium sulfanilamide were added to tubes 1, 2, and 3, respectively. The tubes were then chilled at 2 C for twenty minutes, centri-

TABLE 4—*Observations on the Time of Action of Inhibitors on the Donath-Landsteiner Reaction*

Test tube	Case 1 serum	Control R B C	Compl	Normal saline	Sodium cyanide	Sodium sulfanil amide	Hemolysis
	cc	cc	cc	cc	cc	cc	cc
1	0.5	0.2		0.1			+++
2	0.5	0.2	0.2		0.1		0
3	0.5	0.2	0.2			0.1	0
4	0.5	0.2		0.1			+++
5	0.5	0.2	0.2		0.1		+++
6	0.5	0.2	0.2			0.1	+++

Procedure. Test tubes 1 and 4 are controls. 0.1 cc of saline, sodium cyanide, sodium sulfanilamide added to test tubes 1, 2, and 3 before chilling at 2 C for 15 minutes. Same reagents added to test tubes 4, 5, and 6 after chilling at 2 C for 15 minutes. All tubes then incubated at 37 C for one hour.

fuged in the cold by packing the tubes in ice and the supernatant pipetted off. The cells were then washed in cold phosphate buffer (see table 5). The cells of tubes 2 and 3 were washed in cold phosphate buffer containing 0.008 M concentration of sodium cyanide and sodium sulfanilamide respectively, i.e., in a known effective concentration of inhibitors to prevent any union of hemolysin with the red cells during the washing in the chilled state that might occur as the concentration of inhibitors decreased. The phosphate buffer at pH 7.2 was used to prevent the alkalizing effect of sodium cyanide and sodium sulfanilamide in unbuffered solution. Such a high pH might inactivate complement or elute the hemolysin from the red cell. After washing twice in the above solutions, the cells were resuspended in normal saline and the cell suspensions were then used as shown in table 6. The cell suspensions from each tube represented in table 5 were warmed to 27 C and divided into aliquots of 0.2 cc each. To tubes 1, 3, and 5 were added 0.2 cc of normal saline and to tubes 2, 4, and 6 were added 0.2 cc of complement in the form of guinea pig serum diluted 1 to 5 with saline. The tubes were then incubated at 37 C for one hour.

Results and conclusions. Hemolysis occurred as shown in table 6. This indicated that the effect of sulfanilamide and cyanide on the cells and serum was a reversible one, and also that the presence of sulfanilamide and cyanide in the cold did not prevent the union of the hemolysin with the red cell. The red cells had apparently

become sensitized by the hemolysin in the cold in spite of the presence of the inhibitors. The subsequent withdrawal of the inhibitors allowed the hemolysis to proceed during the incubation at 37 C.

These conclusions were substantiated by the following experiment.

C *Experiment on the effect of sodium cyanide on the union of hemolysin with red blood cells*

TABLE 5—*Observations on Effect of Inhibitors on Union of H. molysin and Complement with R B C (Part A)*

Procedure: Compl and normal saline added to test tubes at room temp (27 C). All tubes then incubated at 37 C for one hour.

To 1 cc of packed Group O cells in three separate test tubes were added 0.5 cc of a buffered 0.08 M sodium cyanide solution (tubes 1, 2, and 4). To another tube (tube 3) of 1 cc of packed red cells, 0.5 cc of saline was added. To each tube were then added 0.2 cc of guinea pig serum and 3.3 cc of the serum of Case 1. One tube containing cyanide (tube 1) was allowed to stand at 34 C. The other three tubes were chilled at 3 C for thirty minutes. Two of the chilled tubes (tube 2 containing cyanide, and tube 3 not containing cyanide) were then centrifuged in chilled containers with packed ice. The contents of the tube (tube 1 containing cyanide) not chilled, were centrifuged at room temperature. The supernatant in the centrifuged tubes were removed and the cells resuspended in 200 cc of saline. The fourth tube (tube 4) containing cyanide, and as a control was incubated at 37 C for one hour following chilling. The supernatant from the tubes 1, 2, and 3, were then dialyzed in cellophane bags against normal saline overnight.

at icebox temperature. The dialyzed supernatants were then used in Donath Landsteiner reactions (see table 7) and titrated for complement. Small aliquots of the cell suspensions were incubated for one hour at 37 C in equal aliquots of Coombs serum and with complement (see table 8).

Results and conclusions Cells chilled in the serum of Case 1 both in the presence and absence of cyanide were agglutinated in the Coomb's test and showed hemol-

ysis on incubation with complement at 37 C after being washed in a large amount of saline (table 8). Employing the dialyzed supernatant from the chilled tubes in the Donath-Landsteiner reaction showed that the hemolysin was absent or present in only a trace. That the hemolysin and complement had been adsorbed and not

simply destroyed by cyanide was shown by the marked hemolytic activity in a Donath-Landsteiner reaction of the dialyzed supernatant from the tubes allowed to stand at 34 C for thirty minutes. Complement was present in that supernatant in a titer of 16 units per cc. That the original cyanide concentration was an effective one was shown by the slight trace of hemolysis in an identical suspension (tube 4) chilled for the same period of time and incubated at 37 C for one hour. Thus, by a second technic, adsorption of hemolysin and complement by the red cell in the presence of cyanide was demonstrated.

DISCUSSION

Both hemolysin and some component of complement were adsorbed by red blood cells from the sera of each of 2 cases in the cold phase of the Donath-Landsteiner reaction. This observation supports some of those reported by Cooke,²⁰ Hoover and Stone,⁸ and by Dennie and Robertson.⁹ Cooke²⁰ has pointed out that although Donath and Landsteiner²¹ maintained the view that cold was necessary only for the union of red blood cell and hemolysin and that complement united in the warm phase, their experiments did not actually prove this. Moss²² concluded that complement did not enter into the reaction of the cold phase (at least not permanently). His evidence consisted of the demonstration of complement in the supernatant serum after chilling with cells. This does not rule out the possibility that some complement was actually used. Hoover and Stone⁸ reported that after chilling red cells in heat-inactivated serum from a patient with paroxysmal cold hemoglobinuria, incubating then in normal serum at 37 C did not cause hemolysis. Washing cells in saline and rechilling and reincubating them in normal saline did cause hemolysis. They interpreted their results as showing a complement factor must also be adsorbed in the cold by cells before they are susceptible to hemolysis on subsequent incubation. Hemolysin and complement in the serum of Case 2 were separable by heat. After inactivating the serum from Case 2 for complement, the hemolysin remained. Chilling and incubating cells in such inactivated serum did not cause hemolysis. Nor did restoring complement to the previously inactivated serum-cell suspension after chilling cause hemolysis. However, rechilling and reincubating at 37 C such a suspension following the addition of complement did cause hemolysis, indicating complement had to be present during the cold phase of the Donath-Landsteiner reaction for the hemolysin to be effective. Therefore, the assumption that complement acts only in the warm phase of the Donath-Landsteiner reaction under these defined *in vitro* conditions is incorrect in at least one instance.

Dennie and Robertson⁹ observed that complement was necessary not only in the cold but also for the warm phase of the Donath-Landsteiner reaction. Although Cooke²⁰ concluded from his work that complement united solely in the cold, some of his observations show that complement was a requisite for the warm phase also. Throughout several of his experiments, cells were chilled in the patient's serum and then resuspended in saline. Cooke reported no hemolysis in such saline suspensions on rewarming. However, if both complement and hemolysin were active only in the cold, then rewarming such saline suspensions should result in hemolysis. Chilling cells in the presence of complement and hemolysin and resuspending them

in either saline or heat-inactivated complement was followed by no hemolysis on incubation at 37 C. Adding intact complement to such warm suspensions, however, did cause hemolysis. Apparently, complement was necessary for the warm as well as the cold phase of the Donath-Landsteiner reaction.

The hemolysin in the serum of Case 1 was inactivated by heating before complement was destroyed. Heating the serum of Case 2 long enough to inactivate the complement did not inactivate the hemolysin. Mackenzie² has also observed differences in the thermostability of hemolysins from various patients with this disease entity, and Yorke and Macfie¹⁰ found the thermolability of the hemolysin in the serum of 1 patient actually varied from time to time.

Several observers have shown that carbon dioxide may be an *in vitro* activating factor in this hemolytic system.^{3,4} As reported previously, when cells were suspended in the serum of Case 1 at 27 C with carbon dioxide in a concentration of 3.6 mEq per liter (pH 6.4) lysis rapidly occurred.¹⁹ The same procedure at 37 C did not cause hemolysis and lysis did not occur even at 27 C if the serum hemolysin had been previously removed. Furthermore, sulfanilamide and cyanide prevented the lysis of a Donath-Landsteiner reaction when this same serum was employed. As the study of other patients' sera had revealed no such effect of carbon dioxide,² it was thought that temperature might have been a critical variable. Thus, workers employing lower temperatures might activate the system with carbon dioxide, while those using higher *in vitro* temperatures might obtain negative results. The upper limit of temperature at which the serum hemolysin becomes effective seems to vary from patient to patient.² As the carbon dioxide *in vitro* effect is dependent on the presence of hemolysin,¹⁹ it seemed logical that the carbon dioxide activity at a given temperature might depend on the thermal amplitude of that particular hemolysin. Although such temperature factors may be important, study of Case 2 suggests that they are not the only ones. At a temperature (11 C) which alone activated the system *in vitro*, the use of carbon dioxide did not increase the amount of hemolysis of cells suspended in the serum of Case 2. Mackenzie had previously reported that carbon dioxide did not activate the *in vitro* hemolytic system of sera from several patients with this disease whom he had studied.² In contrast to the effectiveness of sulfanilamide and cyanide in preventing hemolysis of cells suspended in the serum of Case 1, these inhibitors were ineffective in the prevention of hemolysis of cells suspended in the serum of Case 2. Thus, the effectiveness and ineffectiveness of carbon dioxide, sulfanilamide, and cyanide ran parallel in the hemolytic system.

Sulfanilamide and cyanide in the serum of Case 1 did not prevent the union of the hemolysin and complement with the red cell, but did prevent the subsequent lysis. The adsorption of the requisite serum factors for lysis by the erythrocytes when chilled in both the presence and absence of such inhibitors was shown in two ways. Hemolysin and complement either decreased markedly in concentration, or actually disappeared from the supernatant of all such chilled suspensions. Furthermore, the cells from such chilled suspensions when washed in cold saline and then incubated at 37 C with fresh complement were lysed. This showed the hemolysin had acted on the cell membrane irrespective of the presence of the inhibitors. Lastly, if cells

chilled in the presence of cyanide and hemolysin were washed in saline and then incubated in Coomb's serum, they were agglutinated. This was further evidence that some serum factor had been adsorbed on the red cell. Such agglutination of the cells by an anti-human serum rabbit serum occurred even though the thermolabile components of complement were furnished by guinea pig serum.

The prevention of lysis was not due to an inactivation of the complement necessary during the warm phase of the Donath-Landsteiner reaction. This was established by the lack of effect of the inhibitors when added to the red cell-serum suspension after chilling but before warming. The inhibitors had to be present during the entire Donath-Landsteiner reaction in order to be effective. This suggests the possibility that these substances may be acting at the red cell membrane, and though not preventing the union of the hemolysin-complement complex with the red cell, may, at least in some cases, prevent some subsequent alteration in the spatial configuration of the hemolysin-complement-red cell membrane complex that is a requisite for actual hemolysis. The differences in the effectiveness of these inhibitors might, therefore, be associated with differences in the size of the antibody involved in various sera.

Apparently, the union in the cold of hemolysin and complement with the red cell membrane does not necessarily lead to hemolysis. Some other step must occur. That the latter may be delayed and yet be effective is indicated by the reversibility of the inhibiting effect of cyanide and sulfanilamide. That the inhibiting activity of these two substances does not depend on preventing either the union of the requisite serum factors in the cold or the activity of some additional factor during the warm phase has been illustrated in three ways: (1) Both hemolysin and complement disappear or, at least, diminish in concentration from the supernatant of a chilled suspension containing either of the two inhibitors. (2) This diminution in titer is due to adsorption and not destruction as illustrated by subsequent positive Coomb's tests as well as lysis of the cells when washed and incubated in complement at 37 C. (3) Finally, the inhibitors do not prevent the lysis unless present before chilling. Their ineffectiveness when added only during the warming phase indicates their action is not due to some effect on a serum factor necessary during that phase of the Donath-Landsteiner test.

Thus, by elimination of several possible interpretations, the question arises whether or not by acting at the cell membrane these substances simply prevent reorientation of the antibody-complement complex on the cell membrane. By this concept, the complex could unite with the red blood cell in the presence of the inhibitors and when the latter are removed, reorientation on the membrane could occur and lysis result. In such a concept two possibilities would be suggested: (1) carbonic anhydrase may be contained in the red blood cell membrane and (2) the differences in the effectiveness of the inhibitors from case to case may depend on the difference in the size of the hemolysin molecule in the two sera. Thus, the more thermolabile and possibly larger hemolysin could not reorient itself on the cell membrane in the presence of the inhibitors but the thermostable and possibly smaller antibody could. As a result, the inhibitors would be effective in the first instance and not in the second.

CONCLUSIONS

- Observations made on 2 cases of paroxysmal (cold) hemoglobinuria showed
- 1 Hemolysin and complement were adsorbed by erythrocytes in the cold
 - 2 A thermolabile fraction of complement was necessary for both the cold phase and the warm phase of the Donath-Landsteiner reaction in the serum of 1 case
 - 3 Under specified in vitro conditions, carbon dioxide affected the hemolytic system of 1 case and not that of the other, this carbon dioxide effect was itself subject to the influence of temperature
 - 4 Sulfanilamide and cyanide inhibited the Donath-Landsteiner reaction in the serum of 1 case and not in the serum of the other
 - 5 These inhibitors did not prevent the union in the cold of the hemolysin-complement complex, but did prevent the usual effect of such a union in 1 case
 - 6 If not present during the chilling phase, sulfanilamide and cyanide did not prevent hemolysis
 - 7 Under specified conditions, sulfanilamide and cyanide did not prevent the effect of the thermolabile component of complement in the warm phase of the Donath-Landsteiner reaction
 - 8 The differences in the observations of the 2 cases reported here and some apparent discrepancies cited from the literature suggest the possibility of important fundamental variants in the mechanism of the disease

APPENDIX

Case Histories

CASE 1

W. B. (J. H. H., history number 359265), a 33 year old Negro, was admitted with the chief complaint of upset stomach and dark urine after exposure to cold. The family history was noncontributory. The past history revealed that fifteen years prior to admission the patient had had a penile lesion and was given antiluetic treatment for one and one-half years. The patient dated the present illness as beginning three years prior to admission. At that time, he noted attacks of abdominal cramps, nausea, and vomiting following exposure to cold. These episodes were associated with the passage of very dark urine in noticeably small quantities. The attacks lasted for several hours but the patient thought he could shorten their duration by drinking hot coffee or warming himself. The physical examination was essentially negative. The pertinent laboratory data were as follows: The serologic test for syphilis was positive. There was a mild normocytic anemia. The icterus index was 12. The urine was dark brown. There was a 3 plus albuminuria as well as numerous red blood cells and white blood cells per high power field. The serum nonprotein nitrogen was 71 mg. per cent. The phenosulfonphthalein excretion was 38 per cent at the end of two hours. Urea clearance was 48 per cent of normal maximum. The Donath-Landsteiner reaction was positive. Cold agglutinins were present in a titer of 1 to 160 and were more thermostable than the cold hemolysin. The clinical diagnosis was syphilis associated with paroxysmal (cold) hemoglobinuria and renal impairment.

CASE 2

M. E. (J. H. H., history number 414118), a 30 year old Negro, was admitted with the chief complaint of dark urine following exposure to cold. The family and past histories were noncontributory. The present illness apparently began two years prior to admission with periodic attacks of swelling of the eyelids, lips, periorbital tissues and fingers on exposure to cold. This swelling was associated with itching of the affected parts. The swelling and itching would disappear usually within twenty minutes when the patient became warm. Such exposure to cold would occasionally be associated with mild attacks of

dominal cramps There was no nausea or vomiting One year prior to admission the patient noticed that her urine became red, dark, and almost black after chilling The urine would remain dark for only four to six hours The patient stated that her eyes had been yellow occasionally during the past winter Drinking ice water would result in a tight sensation in her throat No dark urine had been noted following consumption of cold drink or food The physical examination was essentially negative except for slight pallor of the nail beds and mucous membranes The significant laboratory data were as follows The serologic test for syphilis was positive There was a moderate macrocytic anemia The icterus index was 15 Cold agglutinins were present in a titer of 1 to 320 The urine was dark brown and guaiac positive There were occasional red blood cells and white blood cells per high power field The Donath Landsteiner test was positive The clinical diagnosis was syphilis associated with paroxysmal (cold) hemoglobinuria and angioneurotic edema following exposure to cold

THE EVENTS IN THE HEMOLYTIC CRISIS OF HEREDITARY SPHEROCYTOSIS, WITH PARTICULAR REFERENCE TO THE RETICULOCYTOPENIA, PANCYTOPENIA AND AN ABNORMAL SPLENIC MECHANISM

By WILLIAM DAMESHEK, M D AND MARVIN L. BLOOM, M D

HEREDITARY spherocytosis (familial hemolytic jaundice), although a chronic disease of varying severity, at times takes on the aspects of an acute illness. The patient, previously in fairly good health, suddenly experiences malaise, vomiting, fever and nausea. Examination reveals an unusual degree of pallor. In severe instances, a varying degree of shock is present. For these acute episodes, the designation of 'hemolytic crisis' has long been used.

The cause of the crisis has not been determined. If the disease is due simply to the production of abnormal red cells, i.e., spherocytes, and their removal by an essentially normal spleen, the crisis would have to be explained by a sudden great increase in maldevelopment of the bone marrow red cells. This is hardly likely. Both Doan¹³ and Heilmeyer²⁰ have postulated that the spleen is largely at fault, becoming unusually active during the crisis. In a previous report of three cases of crisis occurring successively in members of the same family, one of us⁶ noted a consistent reduction in leukocytes, platelets and reticulocytes. It was speculated that this might be due to an unusual degree of splenic activity with inhibitory effects upon blood formation in the bone marrow. In a more recent article, Owen³⁸ emphasized the pancytopenia and particularly the reticulocytopenia. He suggested that the crisis could not be considered as hemolytic but was actually aplastic and stated that no proof of the hemolytic nature of the crisis was available. The possibility that hypersplenic effects might be present was discounted.

Our observations in seven cases of hemolytic crisis have led us to conclude that the crisis is due to the combination of (1) a marked exaggeration of the usual hemolytic mechanism with (2) arrested maturation of red cells in the bone marrow induced by a pathologically hyperactive spleen. The marrow in crisis shows not aplasia but rather maturation arrest of the nucleated red cells at the most primitive or erythrogonic level. The dramatic and almost immediate effects of splenectomy, with the sudden outpouring of red cells, leukocytes and platelets indicate strongly that the marrow is fundamentally normal but that the spleen has exerted marked inhibitory effects.

It seems likely that the spleen, primarily a passive organ which removes spherocytes selectively, at times becomes unusually active, thus leading to both excessive

This paper is dedicated to Dr. George R. Minor, whose memorable lectures on the physiopathology of diseases of the blood to our class at Harvard Medical School in 1921 did much to stimulate in me a sustained interest in hematology and in the mechanisms of blood formation and destruction. *William Dameshek*

phagocytosis and to hypersplenic inhibitory effects upon the marrow. The crisis may become so dangerous to life that emergency splenectomy may be required. Following splenectomy no further crises develop.

METHODS

Hemoglobin For the most part, photoelectric colorimeter methods¹⁶ were used, utilizing the Cenco and Evelyn instruments. Fifteen and six tenths grams per 100 cc. of blood were considered as the standard of 100 per cent normality.

Serum bilirubin The method of Malloy and Evelyn²⁷ was used with determination of prompt and indirect types. Values of less than 1.0 mg. of bilirubin per 100 cc. were considered normal.

Fecal urobilinogen The average daily urobilinogen output, in a four day stool collection, was determined by the method of Watson.⁴⁹

Reticulocyte and platelet counts These were performed in the same preparations by the method of Dameshek.⁷

Free erythrocyte protoporphyrin This was determined by the method of Grinstein and Watson¹⁷ after a period of observation and practice by one of us (M. B.) in the laboratory of Dr. Cecil J. Watson, University of Minnesota Medical School. The number of extractions performed was in direct relation to the amount of fluorescence seen.

Plasma or serum iron determinations The method of Kitzes, Elvehjem and Schuette²⁴ was used.

Immunohematologic studies Methods for the detection of circulating antibodies, including the use of bovine albumin as a diluent, were utilized as described by Neber and Dameshek.³⁶ Erythrocyte survival time studies were determined by a modified Ashby technic.

Hypotonic fragility The hypotonic fragility was determined in the earlier cases by the method of Daland and Worthley.⁵ More recently, particularly in case B. S., the photoelectric method of Suess, Limentani, Dameshek and Dolloff⁴⁴ was used.

REPORT OF CASES

In 1941, one of us⁶ described three cases of hemolytic crisis which occurred within the same family during a ten day period. These two brothers and a cousin, all of whom lived in the same household, had in common a seventy year old grandfather who was known to have congenital hemolytic icterus. The latter's son, who was the father of the first two patients, also had the disease.

Case 1 D. C. M., 2nd, aged 11, had been known to have chronic jaundice, anemia, and splenomegaly for several years. Mild recurring attacks of fever, weakness, pallor, and increased icterus had occurred about three times annually. On April 13, 1938, the patient suddenly developed pain and vomiting. On the following day jaundice and pallor were noted. Physical examination revealed an acutely ill boy, evidently in mild shock, who showed marked pallor and slight icterus of the sclerae and skin. The temperature was 103.5 F., the pulse rate 120-140 per minute. There was moderate splenomegaly, the spleen being felt 3-4 fingerbreadths below the left costal margin.

Examination of the blood showed hemoglobin, 36 per cent (Sahli), R. B. C., 1.25 M., W. B. C. 3800 per cu. mm. The red cells showed extreme spherocytosis and the average red cell diameter was 5.63 microns. On April 16 the red cell count had dropped to 1.01 M. and an emergency splenectomy was decided upon. The patient was then given large (probably excessive) amounts of intravenous fluids and blood both before and during splenectomy. Immediately following operation, he developed pulmonary edema and expired.

Case 2 R. M. Jr. was a 12 year old boy and the brother of the first patient. Like his brother, he had been known to have had congenital hemolytic icterus for several years. He too had had several episodes (in the spring as a rule) of marked pallor and icterus associated with fever and malaise. On April 21, 1938, he developed fever, malaise, headache, and left sided abdominal pain. On the following day he was dizzy and weak. Physical examination revealed a temperature of 103.6 F., pulse rate 120/minute, the general appearance of acute illness, extreme pallor, slight jaundice, splenomegaly, and grave anemia. The hemoglobin was 30 per cent (Sahli) and the red cell count 1.22 M. The white cell count was 3000 per cu. mm. Extreme spherocytosis was seen and the hypotonic fragility showed beginning hemolysis at 0.64 per

cent NaCl, hemolysis being complete at 0.34 per cent NaCl. At the height of the crisis, it was noted that the reticulocytes numbered only 0.4 per cent. Three transfusions at four hourly intervals were given on April 23 with a resultant rise in hemoglobin to 70 per cent and in erythrocyte count to 3.3 M. Although clinical improvement was noted on the following morning, fifteen hours later, the red cell count had dropped to 2.56 M. Splenectomy was then performed. The next day, sharp increases in both the hemoglobin and erythrocyte levels were noted. Upon discharge from the hospital on May 6 the hemoglobin was 98 per cent and the red cell count 4.46 M. The subsequent course has been uneventful (see table 1).

Case 3. Marjorie McN., aged 5, was the cousin of the first two patients and lived in the same household. Like the others she had been known to have congenital hemolytic jaundice and had had several episodes of apparent hemolytic crisis. On April 22, 1938, she suddenly developed malaise and fever and complained of lower abdominal pain and headache.

4/17/40	4.78	93	8900	1061	0.56-0.42	0.9	1.4	

Examination revealed an acutely ill little girl, with marked pallor and slight icterus. The temperature was 103 F. and the pulse rate 120 per minute. The splenic edge was palpable one fingerbreadth below the left costal margin.

The hemoglobin was 35 per cent (Sahli). The red cell count was 1.7 M and the white cell count 5000 per cu mm. There was marked spherocytosis and the hypotonic fragility test showed beginning hemolysis at 0.80 per cent with complete hemolysis at 0.30 per cent. On the following morning, still at the height of the crisis, only 0.7 per cent reticulocytes were found.

Two transfusions, of 300 cc each, were given on April 26 and 27, following which splenectomy was performed. The spleen weighed 350 grams and showed extreme congestion of the pulp. Convalescence was uneventful. On May 4, the red blood cell count was 4.57 M, the hemoglobin 93 per cent and the white cell count 10,200 per cu mm. The subsequent course was characterized by a definite increase in the mean red blood cell diameter and a diminution of spherocytosis, although an abnormal hypotonic fragility persisted. The subsequent course has been uneventful (see table 2).

Case 4 Mary D S, a 37 year old housewife, was admitted to the J H Pratt Diagnostic Hospital on April 14, 1944, complaining of marked weakness. Pallor had been noted since December, 1943, and the patient's husband had remarked upon the presence of scleral icterus for about a year. She had been asymptomatic, however, until April 8, 1944. At that time she developed malaise, generalized arthralgia and a shaking chill.

Examination revealed moderate fever, jaundice and slight stupor. The pallor became increasingly prominent and was associated with increasing weakness. On admission to the hospital there was barely perceptible icterus, a few petechiae in the region of the uvula and soft palate, and slight lymphadenopathy in the axillae. The heart showed a forceful apical impulse, and appeared somewhat enlarged to left. A grade II systolic murmur was heard at the apex and was transmitted to the base of the heart. The liver edge was tender and palpable 3-4 fingerbreadths below the right costal margin. The splenic edge was felt 3-4 fingerbreadths below the left costal margin. The blood showed hemoglobin, 5.3 Gm (34 per cent), R B C 1.53 M, W B C 6600, reticulocytes 0.3 per cent.

Transfusions totaling 900 cc. were given without reaction and the fever gradually subsided by the sixth hospital day. The reticulocytes rose to 5.4 per cent on the fifth hospital day. No abnormal circulating antibodies were found in the serum (salt solution used as the diluent).

Splenectomy was performed on April 21, 1944. This was followed by an uneventful recovery. The patient was seen last on July 3, 1947, at which time she was in excellent health. Blood studies were completely normal except for persistent spherocytosis (see table 3). Hemoglobin was 12.9 Gm (83 per cent), R B C 4.22 M, hematocrit 38 per cent, M C V 90, reticulocytes 0.8 per cent, platelets 1.73 M, and W B C 12,100 per cu mm. The serum bilirubin was 0.3 mg per cent (indirect).

Case 5 H C, a 14 year old white boy noted vague malaise about March 10, 1946. He complained of severe headache and took a patent medicine containing acetanilid with some relief. On March 16 he suddenly developed sharp pain in the right lower abdominal quadrant, cramp-like in nature, and persisting for several hours. On March 17, the patient felt considerably improved but on March 19 an acute episode of vomiting occurred. On March 20 his physician noted fever of 104 F, a severe nonproductive cough and marked flushing of the skin. The patient was admitted to the hospital on that day.

On admission, he was acutely ill, and appeared weak, flushed and slightly cyanotic. He was apathetic and moderately pale. The oral mucous membranes appeared to be edematous and spongy. Scattered rales were heard at the base of the left lung. The heart rate was rapid but there was no evidence of enlargement and no bruits were heard. Marked tenderness was elicited in the lower quadrants of the abdomen, particularly on the right. The spleen seemed soft and was palpable four fingerbreadths below the left costal

margin. It was extremely tender and there was some spasm of the overlying abdominal muscles. A questionable bilateral Kernig reflex was elicited, there was a suggestion of a bilateral Babinski reflex and meningismus was present. Blood studies showed hemoglobin, 8.9 Gm, R B C 3.10 M W B C 9250.

The question of meningitis was considered seriously on the first day of admission. It was found that the patient had a rapidly progressive anemia. Penicillin therapy was not attended by improvement. On March 21, generalized lymphadenopathy was found. The nodes were bean sized and nontender. A few bleeding areas were noted in the oral mucous membranes, petechiae were present over the anterior chest,

and a generalized morbilliform eruption had appeared. The spleen was palpable four to six fingerbreadths below the left costal margin. Icterus was not noted. The blood examination now showed pancytopenia, i.e. anemia, leukopenia, thrombocytopenia and reticulocytopenia together with an extreme degree of spherocytosis. Actual blood findings were hemoglobin 6.0 Gm, R B C 2.40 M, W B C 3,850, reticulocytes 0.1 per cent.

On the basis of the above findings, the diagnosis of congenital hemolytic anemia in crisis was made. Splenectomy was performed after four transfusions had been given (two on the day of admission, one on

the third day and another just prior to operation) The spleen was greatly enlarged and at least six accessory spleens were present. The course after splenectomy was uneventful; this was particularly striking in view of the very critical condition of the patient before operation.

Case 6 P O N This 26-year-old woman was first seen in October, 1945. The patient came from a known family of familial hemolytic jaundice and represented the fourth generation in which the disease had been known.⁴⁵

Intermittent jaundice had been noted first when she was 15. However, she seemed to be in good health until 1943, a few months after the death of her father of severe hemolytic crisis at the age of 55. At that time she was two months pregnant. She developed chills, fever and became very pale. The question of malaria was considered but malarial parasites were not found. The pregnancy proceeded uneventfully.

although a persistent yellowish tint of the sclerae continued. She complained of fatigue, recurring dizziness and some dyspnea on exertion.

Examination at this time during the sixth month of her second pregnancy elicited slight scleral icterus, moderate splenomegaly, a systolic murmur over the precordium, minimal pitting edema of the ankles and pretibial regions, and some superficial varicosities of the lower extremities. Examination of the blood showed R B C 3,10 M, hemoglobin 65 per cent, W B C 12,500 and marked spherocytosis with increased polychromatophilia and reticulocytes. The pregnancy was uncomplicated by any untoward incidents and a normal child was delivered on January 23, 1946. There was however continued fatigue and intermittent exacerbations in the chronic icterus. Slight pallor, icterus and splenomegaly continued to be the outstanding physical findings. Representative serial laboratory findings are recorded in table 5.

Case 7. The present study was initiated as the result of observations in this case and most of the illustrative figures are based on the data obtained.

Beverly S., a 13 year old white female of Portuguese origin, one of nonidentical twins, entered the J. H. Pratt Diagnostic Hospital on February 21, 1947. She complained of fainting spells, weakness, chills and fever of three days duration. About a week prior to admission she was stated to have contracted a mild upper respiratory infection. Four days before admission, her mother noted pallor. On the following day, the patient complained of dizziness, marked weakness and severe headache. The temperature rose to 104 F that evening. She vomited greenish bitter material and had severe vertigo. Nausea and vomiting persisted, and on the day of admission she was dizzy and very weak.

About one month before this admission there had been an episode of right lower quadrant pain unassociated with nausea or vomiting. Although appendicitis was suspected surgery was not performed. A week before admission another similar episode of abdominal pain occurred shortly after the onset of the last menstrual period. This subsided quickly. Several days before admission, the local physician remarked upon the fact that the patient was jaundiced. Neither dark urine nor light stools had been seen.

It was not possible to elicit any history of familial jaundice or anemia, either in the parents, grandparents, close relatives or in the five siblings.*

The patient had always been noted to be considerably paler than her twin brother. She was a high school student and gave no history of exposure to chemicals or drug ingestion. Fava beans had been eaten occasionally by the family but not for about six months. The past history was irrelevant.

Examination on admission revealed an exceedingly well developed and well nourished girl who appeared very apathetic and critically ill, bordering upon shock. She was drowsy and hardly able to respond to simple questions. There was marked pallor and slight scleral icterus. The temperature was 100 F, pulse 120/minute, and blood pressure 105/50. The examination of the chest was negative. The spleen was readily palpable two to three fingerbreadths below the costal margin. The liver was not enlarged and there was no tenderness in the right upper abdominal quadrant. Representative blood findings are shown in table 6. In brief, at the time of admission they showed hemoglobin 4.0 Gm, (<25 per cent), R B C 1.3 M/cu mm, reticulocytes 0.0 per cent (1), W B C 15,500 per cu mm.

* Inasmuch as no evidence could be adduced in this case for the diagnosis of familial or hereditary spherocytosis, the reasons prompting our diagnosis of congenital spherocytosis deserve mention.

Detailed study of the parents, siblings and relatives was difficult because the patient came from a small town (Provincetown) situated more than 100 miles from Boston.

Through the cooperation of the patient's family physician, Dr. Thomas Perry, of Provincetown, it was found that her father, twin brother and the other two siblings showed no abnormal physical findings. Blood smears which were forwarded to us for examination were within normal limits. The mother was examined carefully but no significant physical or hematologic findings were elicited.

That the disease may be congenital and not familial has been noted, among others, by Wolman⁴⁴ and Race.⁴⁰ The latter observer found one affected child in each of three families although neither the parents nor the siblings nor the close relatives exhibited any evidence of the disease.

Lack of immune iso-antibodies in the blood serum, excellent clinical response to splenectomy, the persistence of spherocytosis, the normal survival time of transfused red cells before splenectomy and the complete lack of any evidence indicating an acquired hemolytic process of well defined etiology tended to support the initial clinical impression of an hemolytic crisis occurring in the course of congenital hemolytic jaundice even though evidence of familial disease was entirely lacking.

Jaundice was not a prominent feature during the hospital course. Very slight scleral icterus was noted during the first two hospital days after which it disappeared. Transfusions of 500 cc, 400 cc, and 500 cc of freshly drawn and citrated blood were administered on the first, second, and third hospital days. On the second hospital day there was slight improvement and following the third transfusion, the patient felt considerably better. At the outset, microspherocytosis dominated the blood smear. The reticulocytes were conspicuous by their complete absence during the first four hospital days despite the severity of the anemia and the hemolytic process. On the fifth hospital day, 0.1 per cent reticulocytes were found and then a gradual rise took place to a peak value of 12.6 per cent on the twelfth hospital day. At no time during the fourteen days of hospitalization did the red blood cell count or hemoglobin concentration approach normal values. Nevertheless, when she was discharged on March 7, the patient stated that she felt as well as she ever had. At that point, the following blood counts were present: R B C 2.76 M, hemoglobin 8.3 Gm (53 per cent), reticulocytes 10.4 per cent.

The patient was followed at frequent intervals and was then readmitted for splenectomy, which was performed on April 16, 1947, by Dr. C. Stuart Welch. Just before the operation the blood counts were as follows: R B C 2.61 M, hemoglobin 8.7 Gm (56 per cent), reticulocytes 10.4 per cent. The postoperative course was uneventful.

On June 23, 1947, the patient was asymptomatic and appeared to be in excellent general health. At this time the blood counts were normal (R B C 4.66 M, hemoglobin 14.6 Gm). When seen on September 5, 1947, the patient was in excellent health and had gained considerable weight. Her mother stated that she had never been so well (see tables 6-10, figures 1-8).

ANALYSIS OF DATA

The Blood Picture

In the report⁶ from this laboratory in 1941, the following comment was made: The reduction in leukocytes, thrombocytes and reticulocytes in the cases reported here appears at first glance somewhat unusual since in the presence of an acute hemolytic process one would expect to find the evidences of increased regenerative activity on the part of the bone marrow, that is, leukocytosis, thrombocytosis and reticulocytosis. As further observations augment experience with the hemolytic crisis, in our own cases as well as in those reported in the literature, it becomes apparent that pancytopenia and reticulocytopenia are usually present.

In case 7, no reticulocytes (figure 5a, table 6) whatever were found at the height of the crisis. In fact, it was not until the fifth hospital day that the finding of 0.1 per cent reticulocytes was recorded. A gradual reticulocytosis then occurred, reaching an initial peak of 12.6 per cent on the thirteenth day of observation. Thereafter reticulocytosis was sustained until splenectomy was performed on the fifty-fifth day of observation. At the height of the crisis, there was also a moderate thrombocytopenia and granulocytopenia (23 per cent segmented and 1 per cent band forms) although the total white cell count was 15,500 per cu mm. By the fifth hospital day when reticulocytes were finally seen the thrombocytopenia and granulocytopenia had disappeared. Thereafter no significant changes in the white cells or platelets were noted until the postsplenectomy period when the expected thrombocytosis and granulocytosis occurred. The platelets have continued at unusually high levels.

The opportunity for such detailed studies was not afforded in the other cases, most of whom were seen under less ideal conditions for investigation. In general, however, these patients pursued a course quite similar to that of the seventh case. Thus in case 1, anemia and leukopenia were present at the height of the crisis.

Table C. Report on the Results of the Blood Transfusions

Day of observation	Date	RBC	Hct	WBC	Granulo-cyte count per mm ³	Granulo-cyte band form	Hct/cr	Reticulo-cyte	Remarks

* The first day of observation coincided with the height of the hemolytic crisis. Transfusions of 500 cc, 400 cc, and 500 cc of freshly drawn and citrated blood were administered on the first, second, and third hospital days. Splenectomy was performed on the fifty-fifth day of observation.

In case 2, anemia, leukopenia and reticulocytopenia (0.4 per cent) were present. The postoperative period was characterized by a great outpouring of red blood

cells and platelets, unfortunately, reticulocyte and other blood cell counts were not available for adequate comparison. In case 3, reticulocytopenia (0.7 per cent), anemia, and leukopenia were present during the crisis. Following splenectomy the red blood cell count rose precipitously and leukocytosis occurred but no parallel reticulocytosis was seen. In case 4, reticulocytopenia (0.3 per cent) was present during the crisis, in addition there was marked anemia, thrombocytopenia and a

FIG. 1. CASE 7 (B. S.) Peripheral blood at the height of crisis, showing the predominance of micro-spherocytes.

normal or somewhat leukopenic white cell count of 6,600. By the fourth day a slight reticulocytosis of 5.4 per cent was present and thrombocytosis was developing.

Splenectomy was followed by a sharp rise in erythrocyte and leukocyte counts, but the data regarding reticulocytes and platelets are inadequate. In case 5, anemia, leukopenia, and reticulocytopenia (0.1 per cent) were present during crisis, and the blood platelets were definitely reduced on smears. In case 6, during a minor hemolytic crisis, the reticulocytes were increased to about 7 per cent but there was a definite leukopenia of between 3300 to 5300.

Extreme spherocytosis was an outstanding feature of the crisis in all our cases. There was very little evidence of the high isic type of blood cell picture seen when large polychromatophilic reticulocytes are also present. The picture is strikingly similar to that seen in the acute hemolytic anemia produced experimentally by large doses of hemolytic antiserum.⁴

FIG. 2. CASE 7 (B. S.) Bone marrow at the height of crisis showing the accumulation of primitive erythroblasts (pronormoblasts, erythrogonocytes) and lack of maturation. The small mononuclear cells are lymphocytes.

In case 7, the Price-Jones curves (figure 6, table 8) of the red cells at the height of the crisis (and before transfusion) demonstrated that about 50 per cent of the red blood cells had a diameter of 4.8 micra or less, almost all the red cells had a diameter of less than 7.0 micra. Seven weeks later and just prior to splenectomy, 37 per cent of the red cells were 6.4 micra in diameter, and 25 per cent of the cells had a diameter of 7.2 to 8.8 micra. Five days after splenectomy, and probably due to an additional release of reticulocytes into the peripheral blood, there was a definite secondary peak at 8.0 micra. This latter figure represented the diameter of 22 per cent of the cells, although over 20 per cent still had a diameter of 5.6 micra.

FIG 3 CASE 7 (B S) Peripheral blood five days following the height of the crisis Demonstrating the appearance of increased numbers of larger red blood cells and the relative or absolute decrease in microspherocytes

or less. Five months after splenectomy the Price-Jones' curve showed a main peak (39 per cent of cells) at 6.4 micra with a wide base due to the persistence of spherocytes.

That the small red cells are truly spherocytes is borne out, not only by their microcytic character and their abnormally dense appearance in the stained blood smear, but by their greatly decreased resistance to hypotonic solutions of sodium

FIG. 4. CASE 7 (B. S.) Bone marrow five days following the height of the crisis. Active progressive maturation of the normoblastic series is demonstrated.

chloride. All our cases of hemolytic crisis showed a greatly increased fragility. Occasionally, slight hemolysis has even been noted in concentrations of sodium chloride solution approaching that of normal saline. Extensive studies of hypotonic fragility were made only in case 7 (tables 1-4, 7, figure 7) in which the determinations were carried out by means of our newly devised photoelectric method.⁴¹ By this method, curves of hemolytic increments, somewhat similar to Price-Jones curves, are obtained. These indicate graphically the different types of red cell population according to their thickness variation.

The blood picture immediately following splenectomy showed a dramatic increase in all the cellular elements. In fact the rapidity of increase of the red cells, white cells and platelets suggested a sudden outpouring of these cells from the marrow to the blood (figure 9)

Bone Marrow Picture

Studies of the marrow by aspirations were performed in cases 2, 3, 4, 6, and 7. The relative time of marrow aspiration differed in these cases. As already mentioned, the conditions for study were ideal only in case 7. However in case 2, marrow was obtained at the height of the crisis and showed a maturation arrest type of erythropoiesis, closely similar to that seen in case 7.

Frequent aspirations of the sternal marrow both during and after crisis were carried out in case 7. At the height of the crisis, when no reticulocytes were found

* Marked microcytosis during crisis indicating extreme degree of spherocytosis and increase in size of red cells prior to splenectomy after termination of crisis.

in the peripheral blood, the marrow preparations showed increased cellularity (figure 2). Granulocytopenia was active and the megakaryocytes were normal both in number and in platelet production. However, there was a striking abnormality of erythropoiesis, indicated by a complete lack of mature orthochromatic normoblasts (Normoblasts 'C') (figure 2). The great majority of the nucleated red blood cells were of the primitive variety i.e. erythrogonies or pronormoblasts. There were only small numbers of basophilic and polychromatophilic normoblasts (types 'A'' and 'B') (see table 9, figures 1 and 2).

From these observations, it was apparent in this case that there was a distinct maturation arrest of the erythropoietic tissue at or just beyond the erythrogonic (pronormoblast) level. On the fifth day, coincidentally with the appearance of a few reticulocytes, another sternal puncture was performed. This showed a normoblastic erythropoiesis with adequate numbers of polychromatophilic and orthochromatic normoblasts, indicating that the arrested maturation had run its course (table 9, figures 3 and 4). In four subsequent marrow aspirations, erythropoiesis continued to be hyperactive and no further evidence of maturation arrest was seen.

Immunohematologic Findings and Erythrocyte Survival Time

Studies of the serum for immune bodies were performed in cases 1 to 4 and in case 7. In the first four cases immune bodies were searched for using normal salt solution as a diluent, but in none of these cases were abnormal agglutinins or hemolysins discovered in the serum. In cases 6, (P O'N) and 7 (B S) iso-anti-bodies were discovered with the use of bovine albumin solution as a diluent, whereas negative results had been obtained using salt solutions. In case 6, (P O'N) an abnormal autohemolysin and isohemolysin, reacting best at 37 C, was discovered with the use of bovine albumin as a diluent, disappearing following the termination of the crisis. The survival time of transfused red cells was studied before and after splenectomy (Figure 8a). The curve of red cell disappearance before splenectomy was definitely abnormal and exponential in type, indicating that the abnormal antibody present was capable of destroying all types of red cells indiscriminately, including the patient's. Following splenectomy the survival time became normal again, coincidentally with the disappearance of abnormal antibody.

TABLE 9—*Bone Marrow Studies: Differential Count of Nucleated Red Blood Cells in Case 7 (B S)*

Date	Granulocyte erythroblast (G:E ratio)	Erythrocytes pronormoblasts	Basophilic normoblast ("A")	Polychromato- philic normoblast ("B")	Orthochromatic normoblast ("C")
		%	%	%	%
2/22/47	3:1	79	20	1	0
2/27/47	1:2	3	8	48	41
3/ 5/47	1:1	7	11	55	27
4/17/47	1:5:1	7	19	62	12
4/25/47	1:5:1	4	8	40	48
9/ 5/47	1:5:1	4	26	59	11

The blood group of case 7 was B, Rh positive. Almost immediately following admission she was given a transfusion of 500 cc. of fresh group O Rh positive blood with added A and B group specific substances (Witebsky). On the second hospital day a transfusion of 400 cc. of fresh group O, Rh positive blood was given with added A and B (Witebsky) group specific substances. During the third hospital day the last transfusion, 1 cc. of 500 cc. of fresh type B, Rh positive blood, was given. No reactions occurred with any of the transfusions. The survival time of the transfused Group O red blood cells was studied by the Ashby technic³⁶ and found to be normal, i.e., 120 days (figure 8b). No transfusions were given in connection with the splenectomy and the disappearance of the transfused cells did not appear to be affected by the splenectomy (see figure 8b). Thus the two cases of hemolytic crisis differed radically with respect to red cell survival time, perhaps indicating somewhat different mechanisms.

Bilirubin and Urobilinogen

Jaundice was not an outstanding feature of these cases in crisis. The available data concerning serum bilirubin have been tabulated with the other blood studies in each case (see tables 1 and 7).

Determinations of the fecal urobilinogen were performed only in case 7. Due to various technical difficulties, this patient's stools were unfortunately discarded during the first eight days of her hospital stay. A four day stool collection was obtained during the succeeding period, when the hemoglobin varied between 7.8 and 8.5 grams per 100 cc. At this time the fecal urobilinogen excretion was 255

FIG 5a CASE 7(B.S.) Graphic representation of two hundred day period of observation, showing the variations in the significant serial studies. The lower graph describes the fluctuations in erythrocyte protoporphyrin and serum iron values.

milligrams per day. This is a definitely high value when related to the hemoglobin concentration, corresponding roughly with the excretion in a normal girl of about 500 mgs per day (normal 100-150 mgs per day). This indicated an approximately threefold increase in blood destruction at that time. Since the patient was improving at that time, it seems reasonable to assume that the fecal urobilinogen output during the first eight days may have been even greater. The two determinations of fecal urobilinogen obtained during the postsplenectomy period were within normal limits.

Erythrocyte Protoporphyrin

The normal range of concentration of free protoporphyrin in the intact circulating erythrocyte has been determined by Grinstein and Watson¹⁷ to be between 15 and 40 gammas per 100 cc of red blood cells, the usual normal value is in the vicinity of 30 gammas per cent or lower

FIG 5b CASE 7 (B S) Close-up of certain values in the first fifteen days of the clinical course

Serial determinations of free erythrocyte protoporphyrin (EP) were obtained only in case 7 (table 10, figure 5). At the height of crisis, at a time when reticulocytes were completely lacking, the EP was 87.8 gammas per cent, well above normal limits. This was perhaps due to an increased erythropoietic activity just prior to the development of the crisis. As recovery from the crisis progressed and reticulocytes appeared in the blood (coincident with marked marrow erythropoiesis) the EP concentration rose rapidly, reaching peak levels of 292 gammas per 100 cc. On the twelfth day of observation, the EP gradually decreased until on the sixty-

eight day it reached a normal value of 2.5 gammas per cent. Following this, it was found that a state of hypoferrremia had developed. This was mirrored, soon later, by a definite increase in the EP. Following the administration of ferrous sulfate, the EP fell again to within normal limits.

FIG. 6. CASE 7 (B S). Price-Jones curves of representative blood smears during the clinical course.

Serum Iron

The concentration of serum or plasma iron and its normal range has been defined by several investigators^{31, 32, 39, 47, 48, 52} as ranging between approximately 50-180 gammas per 100 cc serum or plasma.

In case 7, B S, a serum iron determination at the height of the crisis was 50 gammas per 100 cc concentration, i.e., at the lowest range of normality (see table 10). The patient was not given iron therapy at this time, her only sources of iron being through an unrestricted diet and three transfusions. After the transfusions had been given, a value of 80 gammas per cent was obtained. During the postcrisis

(presplenectomy) period, this comparative plateau of serum iron values seemed to have no correlation with the great fluctuations in free erythrocyte protoporphyrin

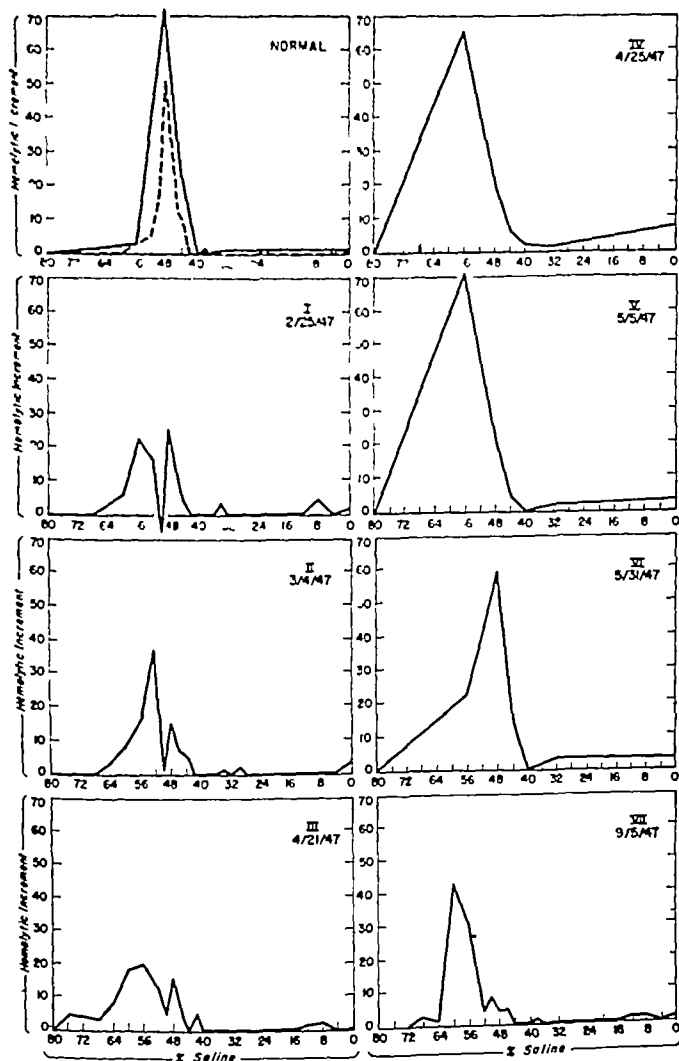

FIG 7 CASE 7 (B S) CURVES OF HYPOTONIC FRAGILITY

Two methods were used to determine the curves illustrated above. These differed only in detail. One involves the use of 29 tubes containing 29 serial saline dilutions from 0.80 to 0.00 per cent NaCl. In each of these the per cent hemolysis was determined, using the Evelyn photoelectric colorimeter. The other uses only 7 tubes, containing the dilutions which have been found to be most critical: 0.80, 0.56, 0.48, 0.44, 0.40, 0.32, and 0.00 per cent. The graph of the normal fragility shows curves from both of these methods, the solid line indicating 29 dilutions and the dotted line, 7 dilutions. Graphs I, II, III, and VII depict 29 tube studies, whereas IV, V, and VI show curves from the 7 tube test.

The hemolytic increment means simply the change in degree of hemolysis from tube to tube as hypotonicity increases (from above, downwards). Therefore, at each point of changing saline concentration, the per cent hemolysis is obtained by the Evelyn photometer, this is compared with the per cent hemolysis in the previous tube, and the per cent difference, or the hemolytic increment, is obtained.

However, two days following splenectomy, a value of 90 gammas per cent was obtained, that this was followed by a sharp drop of the serum iron value to 10 gammas per cent (marked hypoferrremia). At this point the EP values had reached

normal limits and it was predicted that, on the basis of the hypoferrernia, the EP concentration would rise. This actually occurred (table 10, figure 5a).

Ferrous sulfate was then given, and a significant rise in serum iron occurred. It is possible that the drop of the serum iron value was due to the continued depletion of the depot iron stores by the persistent demands of hyperactive erythropoiesis coupled with menstrual iron loss.

DISCUSSION

The Hemolytic Crisis of Hereditary Spherocytosis

Familial spherocytosis is characterized by a chronic hemolytic anemia of variable severity in which spherocytosis and increased hypotonic fragility are prominent features.

The chronic course of the disease is often punctuated by minor and major exacerbations in the intensity of the hemolytic process. Minor episodes are characterized by malaise, low grade fever, increased pallor and icterus. These episodes last a few days or a week, subside spontaneously and quickly, and in fact often go unrecognized.

The major exacerbations may be so severe as to endanger life. Beginning like an acute febrile illness, they progress rapidly with the development of abdominal discomfort, marked pallor, dizziness, nausea and vomiting, chills and fever. Diarrhea may occur and discharges of bile and grossly bile stained stools may be present. During the height of the crisis, the patient may go into shock or a shock-like state, stupor and syncope are common. Examination reveals an extremely sick-looking person, who is markedly pale but only slightly jaundiced. The pulse is rapid and feeble and the blood pressure is often low with a low pulse pressure. The spleen often becomes considerably enlarged, as compared with its previous size, and is frequently tender.

The management of the crisis has been described in a previous paper.⁶ The use of fresh whole blood is of paramount importance. Transfusions not only add red cells but have a well-defined effect on the blood (and plasma) volume. The sudden lowering of the red cell count to levels of 3.5 M to 1.5 M may result in the symptoms of shock. Therefore, appropriately spaced transfusions may be life-saving. It should be noted, however, that transfusions probably have little if any effect on the mechanism of the crisis itself, and may well be overdone. (Overtransfusion was probably responsible in large part for the fatal determination in case 1.) By the judicious use of transfusions and intravenous fluids, an adequate preparation of the patient for splenectomy is possible. This type of management results in a quieter and less 'toxic' patient, and thus in a far better surgical risk and a smoother convalescence.

Another remarkable feature of the hemolytic crisis is its occurrence in rapid succession in several members of the same family. Scott⁴² reported in 1935 the serial onset of acute blood crises in an entire family. In Dedichen's series,¹⁹ reported in 1937, 13 members of 2 neighboring families living in a small town in Norway developed crises within a few days of each other. One of us⁶ in 1941 reported three cases of familial crisis occurring within ten days. In 1945, Horne, Lederer,

Kirkpatrick and Leys²¹ reported hemolytic crisis in the mother and four children of a family of eight, and also in the mother's cousin who lived nearby. In these cases, too, the illness developed in rapid succession in one individual after the other. A few days as a rule elapsed between the onset of the crisis in the various cases.

The occurrence of the crisis in several members of one family and, in two instances, in neighboring families, has naturally led to investigation for an extrinsic cause for the crisis. Thus, in Dedichen's large series,¹² it was suspected that some sort of highly contagious respiratory infection was responsible, at least for initiating the crisis. This appeared to be substantiated by the development of an acute febrile illness in one of the siblings who did not have the congenital hemolytic disease and during the period when the others were having hemolytic crises. Horne *et al.*²¹ placed a ferret in the home of their first family to develop crises in the belief that a virus infection such as influenza might be the responsible agent. The ferret was returned to the laboratory and died shortly thereafter, with symptoms of a nasal discharge and conjunctivitis.

The occurrence of the crisis in families, with 'incubation periods' of a few days between cases, is strong presumptive evidence that an infection is responsible for at least initiating or precipitating the crisis. However, since no real proof of an infectious etiology has been adduced, it is also possible that no infection is present but that fever, rapid pulse, headache, malaise, nausea and vomiting are the results of rapid blood destruction alone.

A final feature of the hemolytic crisis is that it occurs only in the presence of a spleen, i.e., following splenectomy, crises either do not occur or are extremely unusual. This is another indication of the importance of the spleen in initiating crisis (cf. below).

Lowe²⁶ who studied a case during crisis, in which the red cells, hemoglobin, and reticulocytes continued to diminish despite therapy concluded that suppression of marrow function might be responsible. Unfortunately, studies of the marrow were not performed. In the cases of Horne *et al.*,²¹ mentioned above, in which complete lack of reticulocytes was reported at the height of the crisis, a marrow examination was performed in only one case and then on the eleventh day of illness when the patient was improving. These authors referred, however, to a statement by Josephs,²³ who believed, on theoretical grounds, that a depression of marrow activity might be vital to the pathogenesis of the crisis.

Owren³⁸ in a recent comprehensive article reported crises in six cases of congenital hemolytic jaundice and also stressed the occurrence at the height of the crisis of leukopenia, thrombocytopenia, and reticulocytopenia. He was able to study one case before, during, and after crisis and obtained serial examinations of blood and marrow. Owren concluded that there was an erythropoietic 'aplasia' during crisis. He believed that the sudden drop in red cell count occurring in crisis could be adequately explained on the basis of an aplastic reaction on the part of the erythropoietic tissue and went so far as to deny that the factor of hemolysis played any role whatever in the crisis. He suggested that the term 'hemolytic' for the crisis be dropped.

Serial punctures of the marrow in case 7 indicated that the marrow reaction passes through several distinct stages which could be correlated with the reticulocyte picture. During the height of the crisis, when reticulocytes were lacking, the marrow (figure 2, table 9) showed a nucleated red cell population consisting almost entirely of the most primitive cells, i e., erythrogones (pronormoblasts) and some basophilic normoblasts. Several days later and simultaneously with a slight increase of the reticulocytes in the blood, there was a complete reversal (figure 4, table 9) in the marrow picture. Most of the nucleated red cells were of the polychromatophilic ('B'') variety. Later, as the reticulocyte peak had passed and the

marrow picture was that as ordinarily seen in congenital hemolytic jaundice, most of the normoblasts (table 9) were of the mature variety. Thus the reticulocytopenia of the crisis could be explained adequately by a maturation arrest of the nucleated red cells of the marrow at the erythrogonic level, with a resultant lack in the production of mature non-nucleated erythrocytes.*

* The large primitive red cells seen in the crisis have been referred to by some observers³⁷ as megaloblasts. The concept of what a megaloblast is has been confused in the literature, in our laboratory this term is used for the nucleated red cell series as seen typically in pernicious anemia and related states. The nucleus of the megaloblastic cell retains a relatively primitive chromatin mesh (which recalls that of the reticulum cell) until just before pyknosis. The identity of the megaloblastic series has been discussed by Jones.²² Our studies indicate that the preponderant nucleated red cell—seen in the bone marrow during crisis—is not a megaloblast but is a primitive red cell of the erythrogonic (pronormoblast) type. What

The maturation arrest of the nucleated red cells in the bone marrow is apparently not paralleled by an arrested maturation of the granulocytes, which indeed appear to be increased in number, both in an absolute as well as a relative fashion. Furthermore, the relative proportions of the different types of granulocytes in the marrow are within normal limits, suggesting that a maturation defect of these cells is lacking. These findings in the marrow, in association with the leukopenia and granulocytopenia of the peripheral blood, might indicate that a "block" phenomenon is present, i.e., although maturation of the granulocytes is proceeding in a normal fashion, the mechanism controlling their delivery from the bone marrow to the blood is perhaps defective.

Such a phenomenon occurs typically in various types of splenomegaly in which a possibly exaggerated activity of the spleen, i.e., hypersplenism,¹⁰ is present.

TABLE 11—Comparison of Blood Counts during Crisis in the Seven Cases

Case	R B C	W B C	Reticulo cytes	Remarks
	millions/cu mm	thousands/cu mm	%	
I D C M Jr	1.25	3800	—	Minor hemolytic crisis
II R M Jr	1.22	3000	0.4

V H C	2.40	3850	0.1	
VI P O N	3.24	3300	7.6	
VII B S	1.3	15500 30% gran- ulocytes	0.0	

This is present in such diverse conditions as portal hypertension (cirrhosis of the liver), chronic infectious splenomegaly, including malaria, syphilis, tuberculosis, rheumatoid arthritis and Boeck's sarcoid, Gaucher's disease, various primary neoplasms of the spleen, and finally in many cases of "idiopathic" splenomegaly. Leukopenia, neutropenia and thrombocytopenia, i.e., pancytopenia, are present, although the bone marrow itself is hyperplastic. Occasional cases of "hypersplenic" hemolytic anemia show low reticulocyte counts with a well-defined maturation arrest of nucleated red cells at the erythrocyte level. In these cases, and from an analogy with other instances of hypersplenism,¹⁰ we have come to the conclusion that the hemolytic crisis is based on a suddenly developing splenic disturbance. This, in turn, may be of infectious origin. No definite evidence of infection has been advanced as yet, but the occurrence of successive cases in the same family is strong presumptive evidence of this possibility. Doan^{13, 14} contends that the splenic hemolytic mechanism may be readily unbalanced with the result that numerous minor crises may develop during an individual's lifespan. This might develop, for example, in the presence of certain acute infectious states.

little maturation occurs beyond this primitive stage is productive of a normoblastic and not of a megaloblastic type of erythropoiesis.

FIG 8a CASE 6 (P O N) Survival studies (Ashby technic) during crisis and after splenectomy The red cell survival time was diminished during crisis, and became normal after splenectomy

FIG 8b CASE 7 (B S) The rate of disappearance of the transfused red blood cells pursues a straight line course, i.e., normal survival time

It is possible that the postulated splenic abnormality leads (a) to an increase in hemolytic activity with resultant extreme spherocytosis and rapidly progressive anemia, and (b) to various inhibitory "hypersplenic" effects. Such effects upon the

bone marrow might result in, (a) a "block" phenomenon in which granulocytes are prevented from being delivered normally to the circulating blood, (b) a reduced production of platelets from megakaryocytes and, (c) in maturation arrest of red cells at the erythrogonic (pronormoblast) level. These phenomena would lead to reticulocytopenia, leukopenia, granulocytopenia, and thrombocytopenia. Thus, the various features of the hemolytic crisis may be conceived of as being due to an extreme degree of hypersplenism, causing simultaneously both excessive

COMPARATIVE BLOOD COUNTS BEFORE & AFTER SPLENECTOMY

FIG. 9. Comparative blood counts before and after splenectomy in cases 3-6, 7. The darkened portions represent the period immediately preceding splenectomy. In the white columns are the values obtained immediately following splenectomy. Reticulocyte and platelet determinations are included only in case 7.

hemolysis and maturation arrest of the nucleated red cells. This would naturally lead to an extremely rapid development of anemia (figure 10).

The exact mechanisms by which blood becomes destroyed during the hemolytic crisis remain quite obscure. There is no evidence of intravascular hemolysis as indicated by hemoglobinemia and hemoglobinuria. The finding of abnormal iso-antibodies in two of our cases (autohemolysin in case 6, autoagglutinin in small concentration in case 7) suggests an immune body type of autohemolytic activity, as described in previous papers.

This is confirmed by an abnormal survival time of transfused red cells in our case 6. No evidence of erythrophagocytosis is evident in the studies of splenic

histology The chief histologic feature of the removed spleen is the great 'pooling' of blood within the pulp which shows large numbers of ghost cells and cells in various stages of hemolysis with the sinusoids appearing to be almost empty. It would appear that the blood has largely left the sinusoids for the pulp where it is 'trapped'. It is possible that an infection may so alter the capillary permeability of sinusoids that blood "leaks" from them into the pulp where various mechanisms

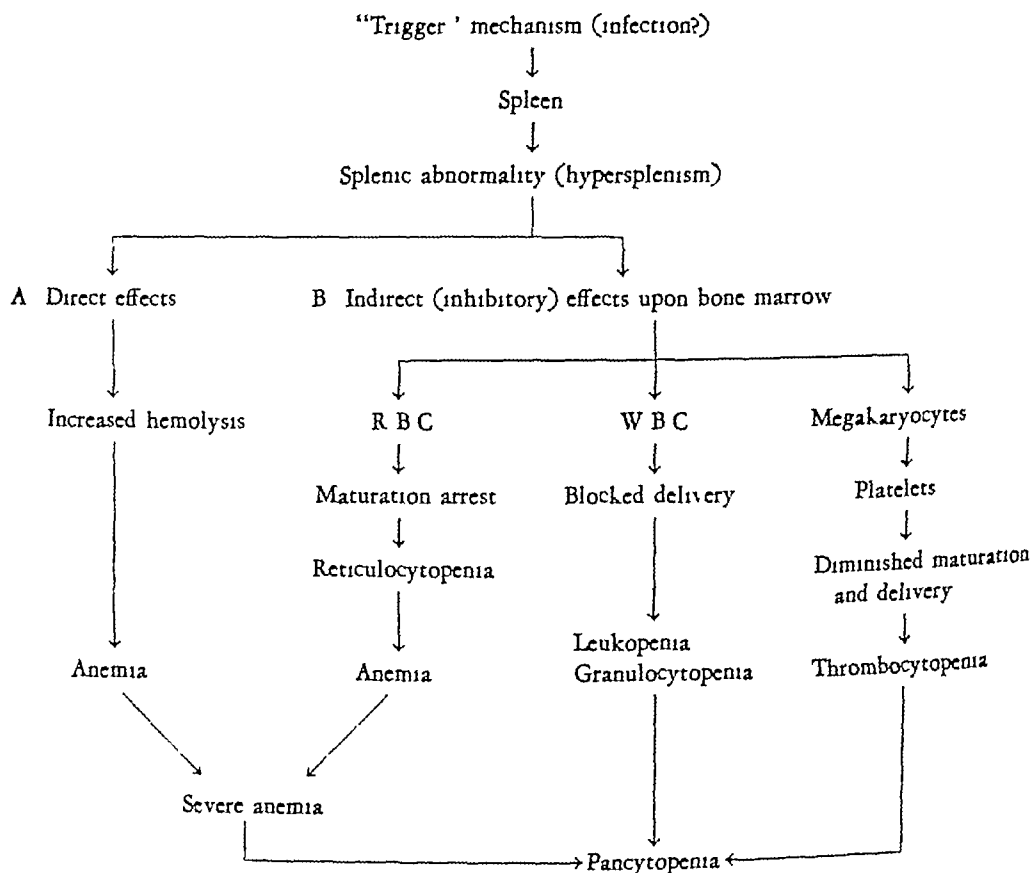

FIG 10 —THE HEMOLYTIC CRISIS

such as erythrostasis, mechanical trauma, and abnormal antibody activity might combine in the destruction of excessive numbers of red cells

We do not believe, as Owren²⁸ maintains, that the events in the hemolytic crisis can be explained on the basis of a suddenly developing marrow aplasia. In the first place, the marrow is by no means aplastic. Secondly, the marrow is evidently capable of an extremely rapid increase in activity when the spleen has been removed. This is borne out by the sudden rise in red cells, white cells, and platelets which occurs after splenectomy. This is due, we believe, to the removal of a highly deleterious organ, having inhibitory and phagocytic effects. Furthermore, Owren's concept does not explain the extreme degree of spherocytosis which regularly occurs during crisis and which indicates, according to our investigations,

a marked degree of hemolytic activity. Studies of the fecal urobilinogen should settle this problem. These were not carried out by Owren, nor in our own series, except in case 7, where it was distinctly elevated. Dr. Jonah Li (University of Oregon Medical School) recently studied a family of five individuals having hemolytic crises occurring within ten days of each other. All the cases showed blood pictures similar to those described above, with extremely low reticulocyte values. In two cases, fecal urobilinogen determinations at the height of the crises, showed values that averaged approximately 1500 mgs per day, i.e., about 20 times the normal value, taking into account the severe anemia. At the termination of the crises, the fecal urobilinogen values became very low.

A final indication of the direct relationship of the spleen to the crisis is the complete disappearance of all tendency to crisis following splenectomy. Whereas before operation the red cell count is subject to well-defined and even to marked fluctuations, this does not occur following operation. Spherocytosis continues to be present but the sudden extremes in this abnormality in association with a greatly increased anemia, do not develop. This is another indication that the spleen has an active influence in blood destruction and in initiating the various events of the hemolytic crisis.

The Possible Relation of the Events in the Hemolytic Crisis to the Normal Hemolytic Activity

The sudden development of extreme spherocytosis and extreme red cell destruction in the crisis suggests strongly an extrinsic activity, i.e., a factor outside the marrow resulting in changes affecting the non-nucleated red cell. The theory most commonly held for the spherocytosis of the familial disease is that it is the product of an abnormal type of erythropoiesis. Since spherocytosis is most marked in the crisis, one would expect to find some evidence of this abnormality in the bone marrow. However, this is by no means the case, either in the chronic form of the disease or during the crisis. In the chronic form, the marrow shows marked erythroblastic hyperplasia, maturation is orderly, and a gradual reduction in size of the nucleated red cells occurs as the mature orthochromatic stage is reached. No evidence for the development of spherocytosis can be seen in the first stages of the life span of the non-nucleated erythrocyte (i.e., the polychromatophilic red cell) in which the cells show a diameter greater than normal. The discrepancy between the relatively large polychromatophilic reticulocytes and the small orthochromatic spherocytes is quite striking, suggesting that some abnormal mechanism modifies the rather young circulating erythrocytes making them spherocytes. This is noted, even more strikingly, in acute acquired hemolytic anemia with abnormal iso-antibodies and can be reproduced experimentally.

In the extreme degrees of spherocytosis, as seen in the hemolytic crisis, one would expect, if the theory of a bone marrow abnormality were correct, to find an extreme degree of spherocytic development in the marrow. Instead the marrow shows very large primitive cells with an almost complete maturation arrest. We believe that this can only indicate that the spherocytes become spherocytic outside the marrow perhaps by some sort of abnormal intravascular mechanism. Since the crisis may

represent an exaggeration of the normal hemolytic mechanism and since spherocytosis is so marked in the crisis, we believe that the spherocyte does not necessarily indicate an inherent defect of erythrocyte formation, but rather the end result of an abnormal type of hemolytic mechanism

That abnormal iso-antibodies are not found customarily in familial spherocytosis, does not rule out their presence. These antibodies may be of such minor intensity or adsorbed in some fashion to the red cell surface, as to make their detection difficult by methods now available. The failure to find abnormal antibodies need not necessarily indicate that they are lacking since methods for their detection may still be imperfect. In the past two years alone, two new methods have been introduced: the use of bovine albumin as a diluting medium and the Coombs antiglobulin test. These tests have resulted in the frequent finding of hemolytic antibodies, undetected by methods previously in use. They suggest that, with the years, other methods, even more sensitive, may become available.

Similar reasoning holds true for the normal life span of red cells introduced into the circulation of an individual with the disease. The fact that the "foreign" red cells are not destroyed more rapidly than normal has led to the widespread conception that the disorder must therefore be due to an inherent defect of the individual's own red cells. This need not necessarily be true since the abnormal hemolysis may be autospesific (i.e., active only against the individual's own red cells). Furthermore, our finding in one case of crisis, of a greatly diminished red cell survival time (see figure 8a, case 6) might indicate that in crisis the hemolysin activity may become so outspoken that it will not only cause a rapid destruction of the individual's own cells but also result in an exponential type of destruction of introduced "foreign" cells.

SUMMARY

The course of hereditary spherocytosis (congenital or familial hemolytic anemia) is subject to major or minor exacerbations or crises. Pancytopenia, reticulocytopenia, and extreme spherocytosis characterize the major crises, during which hypersplenic effects appear to play a major role. These are characterized by the combination of (1) an unusual degree of hemolysis with (2) inhibitory effects upon maturation and delivery of bone marrow cells. At the height of the crisis, an extreme degree of maturation arrest in erythropoiesis is present. Splenectomy, which is often urgently necessary, results in a very rapid increase in all the cellular elements of the blood, confirming the phagocytic and inhibitory effects of the abnormal spleen. Following splenectomy, no further crises occur. The presence of successive cases in the same family suggest the possible role of infection as a precipitating or trigger agent in initiating an abnormal splenic mechanism leading to crisis. The cause of the hereditary spherocytosis is commented upon and evidence bearing upon an autospesific mechanism is discussed.

JAUNDICE AND THE SULFONAMIDE DRUGS

By CHARLES H. RAMMELKAMP, M.D.

IT IS NOW well established that jaundice is one of the toxic manifestations of sulfonamide chemotherapy. Although it is usually possible to recognize this complication, sulfonamide-induced jaundice may be difficult to differentiate from toxic hepatitis occurring as a complication of the infectious process itself as well as from sporadic instances of infectious hepatitis and serum jaundice. Since the sulfonamide drugs are widely used in medical practice, it is perhaps of some interest to review the distinguishing characteristics of toxic hepatitis caused by these compounds. The establishment of a definite diagnosis in jaundiced patients is important because all sulfonamides should be discontinued immediately if this form of chemotherapy appears to be responsible for the toxic complication. In individuals with jaundice due to other causes, sulfonamide medication, especially sulfadiazine, may be given without causing further damage to the liver parenchyma.¹

In general, three forms of jaundice may accompany the use of the sulfonamide drugs. They may be classified as immediate, intermediate and delayed, depending upon the time of appearance of toxic symptoms, including icterus, following the initiation of therapy.

IMMEDIATE JAUNDICE

The immediate form of toxic hepatitis secondary to sulfonamide medication is usually readily recognized. Within a period of one to three days from the time chemotherapy is started, jaundice appears. Prior to this, however, and usually within a few hours after the initial dose of sulfonamide, other toxic symptoms appear. These include nausea, vomiting, headache, chills, fever, burning of the eyes, and skin rashes. As the drug is continued the skin may become icteric and the urine dark with bile. Examination usually reveals an enlarged tender liver as well as various forms of skin rashes. The erythrocyte count and hemoglobin concentration are usually normal and the reticulocyte count is not elevated. The leukocyte count may be elevated or normal.

These patients give a history of previous ingestion of one of the sulfonamide drugs, and usually state that toxic symptoms occurred at that time.² An example of this form of hepatitis is reported below.

CASE REPORT

A 45 year old married woman entered the Evans Memorial, Massachusetts Memorial Hospitals on September 14, 1940, because of chills, fever, and nausea of three days' duration.* About eight months prior to admission she noticed that her afternoon oral temperature occasionally reached as high as 99.6 F.

From the Departments of Preventive Medicine and of Medicine, Lakeside Hospital, Western Reserve University, Cleveland, Ohio.

* I am indebted to Dr. Chester S. Keefer for permission to report this case.

and, because of accompanying weakness, she reported to her physician. A diagnosis of endocervicitis was made and she was advised to enter the hospital for study. On July 28, 1940, she was admitted to another hospital where a blood culture revealed *Staphylococcus albus*. She was given sulfathiazole, 1 gram every 4 hours, beginning on August 10, 1940. The hospital record shows that the blood cultures became sterile and she was discharged on August 17. She continued to take sulfathiazole and, on August 24, two weeks after the institution of chemotherapy, she complained of photophobia, lacrimation and soreness and redness in several old scars around the left shoulder. Later a rash developed around the eyes and over the legs. Because of these findings the drug was discontinued by her physician with subsequent disappearance of all symptoms.

Because she continued to exhibit a low fever of about 99.2 F, on September 11, 1940, her physician again started sulfathiazole therapy. At 10 a.m. and 2 p.m. she took 1 gram. At 4 p.m. she developed a chill with a subsequent rise in temperature to 103 F. No further sulfathiazole was ingested until the following day when the dosage was increased to 1.5 grams. Again she took the drug at 10 a.m. and 2 p.m., but after the latter dose she developed a rigor, the temperature rising to 104 F. The next day she complained of a severe headache, aching in the joints, nausea, and vomiting, and noticed that her urine had become quite dark in color. She was hospitalized because it was thought she had developed hematuria.

The patient gave a history of tonsillitis in 1936 for which she had received sulfanilamide without the development of toxic symptoms.

On admission to the hospital the oral temperature was 100 F. There was a definite icteric tint to the skin and sclerae. There were no petechiae and no rash. The vessels of the conjunctivae and sclerae were injected. The nasal and pharyngeal mucous membranes appeared normal. The lungs were clear to percussion and auscultation. The heart was normal in size, no murmurs were heard. The liver edge was tender and extended 2 centimeters below the costal margin. The spleen was not felt.

Laboratory examinations included a total erythrocyte count of 4,000,000 per cubic millimeter, a hemoglobin of 71 per cent, and 4,200 leukocytes per cubic millimeter. The differential count on the blood smear showed 68 per cent neutrophils, 21 per cent lymphocytes, 2 per cent monocytes and 9 per cent eosinophils. There was bile in the urine as well as a trace of albumin.

Clinical course. The patient improved rapidly during the period of hospitalization. The icterus index which was 25 on September 16, 1940, had fallen to 4 on September 24. Bile was not detected in the urine after the third day in the hospital and the urobilinogen, which was present in a 1:20 dilution, decreased so that it was found only in undiluted urine. The reticulocyte count was 0.6 per cent on September 18 and the erythrocyte count and hemoglobin concentration did not change significantly. The Takata-Ara test was positive and there was a slight depression in the hippuric acid excretion test.

Because it was felt that this patient's illness was caused by sulfathiazole, she was given 0.5 gram on September 24, 1940. One hour later she developed a rigor, the vessels of the conjunctivae and sclerae became congested, she vomited twice, and complained of headache and soreness in the scars on the left shoulder. Four hours after the ingestion of the test dose of sulfathiazole the temperature reached 105 F. She was then given an intravenous infusion of 2000 milliliters of saline and the temperature rapidly returned to normal. No bile was detected in any of the urine specimens, but the icterus index gradually increased to 10 during the subsequent 24 hours. Urobilinogen was found again in dilutions of 1:20.

To summarize this case, the patient received an initial course of sulfathiazole and developed toxic symptoms two weeks later. These symptoms included nausea, vomiting, episcleritis, chills, fever, and skin rash. The drug was discontinued for approximately seventeen days and upon its resumption immediate toxic effects were exhibited. From the history it appears that jaundice developed two days after the first dose of the second course of sulfathiazole. When she had recovered, a test dose of 0.5 gram of sulfathiazole was administered. Again she developed fever, nausea, vomiting, and episcleritis. The icterus index rose from 4 to 10 and remained elevated for forty-eight hours. This patient's illness is an example of immediate jaundice due to previous sensitization to the sulfonamide drugs. There was little

evidence of hemolytic anemia although, from the studies recorded, it is not possible to state that some increase in the rate of destruction of the erythrocytes did not occur

INTERMEDIATE JAUNDICE

This form of jaundice is associated with a mortality rate of 5 to 10 per cent³ and is readily diagnosed as sulfonamide-induced since it is secondary to acute hemolytic anemia as well as to toxic hepatitis. The anemia usually becomes prominent enough to cause pallor, weakness, dyspnea, and nausea and vomiting in about two to five days after the institution of therapy,⁴ although occasionally it may occur later.⁵⁻⁶ Soon after the development of the acute hemolytic anemia, jaundice may appear. This is believed to be due not only to the very great destruction of erythrocytes, but also to some direct action on the liver cells.⁷

The clinical features of this form of jaundice are readily recognized. The patient invariably becomes critically ill during a period of a few hours, pallor is marked, the liver and spleen may be enlarged, and fever is usually present. Hemoglobin may appear in the urine. Later biliuria and urobilinogenuria are observed. The erythrocyte count and hemoglobin concentration are low, and a smear of the blood may show nucleated erythrocytes as well as variations in the size and shape of the cells. The reticulocyte count becomes markedly elevated. There may be spherocytosis and an increased hypotonic fragility during the acute phase of the disease.³

The total leukocyte count is usually markedly elevated, counts of 100,000 per cubic millimeter not being unusual. Immature cells are observed, as well as an increased number of eosinophils. The blood usually contains free hemoglobin as well as increased amounts of bilirubin.

It is apparent from this description that this form of sulfonamide jaundice should be easily recognized. It occurs most frequently following sulfanilamide medication although sulfathiazole, sulfapyridine and sulfadiazine occasionally cause acute hemolytic anemia and jaundice. When such toxic reactions occur, the drug must be stopped immediately and treatment, including blood transfusion, instituted.

DELAYED JAUNDICE

Jaundice may appear ten or more days after the institution of sulfonamide treatment. Under these circumstances, the diagnosis of sulfonamide hepatitis may be difficult since jaundice may develop during the same period as a complication of the infectious process itself. Generally, however, in those patients whose jaundice is secondary to chemotherapy there are other associated toxic symptoms and physical signs.⁸

It is the usual experience that this form of hepatitis develops at about the time clinical improvement is anticipated. The temperature, which may have been normal or somewhat elevated, suddenly increases. In some instances it may be septic in type and associated with severe chills. Nausea, vomiting and epigastric discomfort may be prominent. Other symptoms of toxicity include headache, dizziness, photophobia, and aching of the joints. A distinctive feature which is of considerable aid in the establishment of the correct diagnosis is the appearance of

a rash which may be erythematous or, at times, exfoliative in character. Erythema nodosum is not infrequently observed in patients treated with the thiazole derivatives of the sulfonamides. Jaundice develops within a few hours or days after these other toxic symptoms have become manifest.

The physical signs and abnormalities in the laboratory examinations are similar to those found in patients developing the immediate form of jaundice. The liver and spleen may be enlarged and occasionally ascites may develop.² There may be a moderate anemia, especially if the reaction occurs after the ingestion of sulfanilamide. Usually there is an increase in the total leukocyte count, which may be marked when there is an extensive rash, and occasionally there may be leukopenia. The bilirubin content of the blood is increased and urobilinogen and bile are found in the urine. Impairment of liver function may be demonstrated by several tests.

Although most patients receiving sulfonamide therapy and developing the delayed form of jaundice conform to the above description, there are a few in whom the diagnosis is difficult. Toxic hepatitis apparently may develop several weeks after the cessation of chemotherapy. Garvin² reports an instance where jaundice and exfoliative dermatitis developed forty-three days after all sulfonamide medication had been stopped. In some patients jaundice appears as the only toxic manifestation of chemotherapy. One patient² developed jaundice sixteen days after sulfanilamide therapy was instituted and no other symptoms were recorded. In this instance the patient was being treated for chronic prostatitis, so that it would appear improbable that the hepatitis was secondary to the infectious process.

DISCUSSION AND SUMMARY

It is apparent from a review of the reported cases of hepatitis associated with sulfonamide therapy that it is usually possible to recognize this toxic manifestation. This is of considerable practical importance since, in every instance in which the sulfonamide is responsible for the jaundice, treatment with the drug should be discontinued and some other form of therapy, such as the antibiotics, instituted. If the jaundice is not secondary to the sulfonamide, therapy may be continued even in the presence of hepatitis secondary to the infection.¹

Jaundice which appears during the first week of chemotherapy is usually associated with a previous history of ingestion of sulfonamides and accompanying signs of toxicity (immediate sulfonamide jaundice) or with acute hemolytic anemia and jaundice (intermediate jaundice). In either instance the diagnosis is not difficult because the clinical and laboratory abnormalities are characteristic. Finally, jaundice which occurs after ten days of chemotherapy is usually associated with other toxic manifestations, especially fever and various forms of rashes (delayed jaundice). Occasionally jaundice may be the only toxic manifestation of sulfonamide therapy and, in such patients, a definite diagnosis may be difficult.

BLOOD AND BONE MARROW IN INFECTIVE SUBACUTE AND CHRONIC ATROPHY OF THE LIVER

By E. MEULENGRACHT, M D , AND H. GORMSEN, M D

INTRODUCTION

NUMEROUS investigations have been made of the blood picture and bone marrow in hepatic diseases, particularly in cirrhosis of the liver. These have revealed that especially in cirrhosis of the liver, macrocytic anemia frequently develops. This can be accepted as a well-ascertained fact.^{4 5 21}

It has further been shown that in liver diseases, especially in cirrhosis, changes also occur in the bone marrow. One sees rather frequently a slight or moderate increase in the number of erythroblasts, possibly a shift to the left in the erythroblasts, often a fair number of large forms, but no megaloblastic change in the marrow. There is also some increase in the plasma cells, and possibly also in the reticulum cells, with or without pigment. More rarely a slight myeloid hyperplasia or a slight eosinophilia are observed.^{6 7 12 13 15 20}

As numerous cases of a special fatal form of subacute and chronic infective hepatitis have occurred in recent years and continue to do so here in Denmark, we have had the opportunity of examining the blood and bone marrow in this particular form of liver disease. The following notes deal with the nature of these cases.

In 1943 and 1944, subacute and chronic hepatitis began to occur in our clinic and in all other clinics in Denmark. Appearing suddenly, and so extensively and with such malignant symptoms, it produced the impression that an entirely new disease had arisen, and soon came to be known among both doctors and laity as "the malignant and dangerous jaundice." The most striking fact is that the patients were almost exclusively women of from 40 to 70 years of age.

The clinical picture is dominated in these cases by long-continued jaundice. It is, as a rule, only slight, but can be more intense or even severe. It varies somewhat in intensity, with a tendency gradually to subside, but in its place ascites and edema make their appearance in many cases in a few months' time, though usually in six months or a year, frequently at the stage when the jaundice has greatly decreased. After a longer or shorter interval, hepatic failure and death finally supervene. The prognosis is very grave, almost all the patients dying of the disease sooner or later.

At autopsy, a small contracted liver with isolated remains of liver tissue and an extensive development of coarse connective tissue is found, a picture previously described,² among others, in 1930 during a Swedish epidemic.

Preliminary reports have been published on the numerous cases,^{1 3 9 10} and a more comprehensive joint report will appear in the near future. The disease must presumably be regarded as a form of acute infectious hepatitis, the extensive epidemic of which in Denmark reached its climax in 1944.

From Medical Dept. B, Bispebjerg Hospital, Copenhagen, Denmark.

MATERIAL

The material which we have ourselves intimately studied is based on 24 women with subacute and chronic infectious hepatitis of the type described above. Their ages varied from 40 to 80 years. The history of the disease, when the investigation

took place, varied from 1-15 months duration. In other words, such an interval had elapsed since the jaundice was first noticed, but as, in a number of these patients, the disease developed rather insidiously, it had probably lasted as a rule longer than the specified period. Some of the patients had ascites and edema at the time the investigations were made, others developed these symptoms later. Some died shortly after the investigation, but most died later on.

Besides the above material, we have had access to other cases of the disease

approaching 150 in all, and from their records we have been able to collect further information about the blood changes

METHODS

All the blood examinations were made by two well-trained technicians

The icteric index was determined by Meulengracht's method. The hemoglobin was estimated in an Autenrieth-Königsberger colorimeter, standardized to 100 per cent = 18.5 per cent oxygen binding capacity determined by Van Slyke's method.

Dilution of the blood for counting was done according to Ellermann's principle with separate pipets and mixing tubes, the blood corpuscles were enumerated in Zeiss counting chambers. The color index determinations were reckoned on the assumption that 100 per cent Hb corresponds to 5,000,000 red blood cells. With these methods and standards we find the color index in normal persons to be about 1.1.

The mean diameter of the red blood cells was determined by Gram's method, where they are measured in their own serum, so that one can be sure of avoiding the changes which may occur on drying or washing in foreign media. A drop of blood is sucked up by capillary attraction into a 5-10 cm. long, thin glass tube (capillary tube of about 1 mm. thickness). The tube is sealed at both ends and put aside for some hours. The blood has then clotted, and the serum has separated at the side of the clot. In this serum, free blood corpuscles are present in sufficient quantities for measurement and in suitable numbers so that measurement is not impeded by the corpuscles lying too close to one another. After the ends have been broken off the tube a small drop of serum is blown out into a counting chamber of half the usual height and is covered with a thin cover glass. The measurements are made with the help of an ocular micrometer and immersion lens. The diameters of 100 blood corpuscles at random are measured and the mean diameter calculated. Mulberry shaped, spherical and other abnormally shaped blood cells are avoided.

The Takata reaction was performed by Jezler's modification. The blood sedimentation rate was determined by Westergren's method.

In the smear preparations of the sternal punctures, a differential count of 200 cells was made. Further more, in every case a section of the coagulum of the sternal puncture after embedding in paraffin was examined.

The investigations of the sternal punctures were all made by one of us (H. G.)

RESULTS

Blood. In table 1, the age, sex, duration of the disease and the results of the blood examinations are given for those patients we ourselves thoroughly investigated.

The icteric index varied from 7 to 135, it often became decreased as the cirrhosis progressed. The Takata reaction in most of the patients was strongly positive (+++), but in some it was weaker (+ or ++). In one case it was negative, but it is possible that the diagnosis was wrong. The blood sedimentation rate was increased in all the cases investigated.

The hemoglobin values varied from 50 to 105 per cent, red blood cells, from 2.17 millions to 4.65 millions. In most cases, there was some anemia. The color index varied from 0.8 to 1.36. It was usually around 1.1, which with our standards corresponds to the normal, in a few cases it was perceptibly diminished. On microscopic examination of the stained dry preparation, neither oval cells nor large ones of the nature of megalocytes were observed. From the other more extensive material we have had access to, we have collected 141 determinations in 75 patients. Hb varied from 58 to 104 per cent, R. B. C. from 2.5 millions to 5.1 millions, color index from 0.8 to 1.34. In figure 1 the Hb values are plotted against the red cell values, and the color index given. It will be seen that there is a marked tendency to a moderate degree of anemia, the bulk of the values lying between 60 and 80 per

cent Hb, and between 3 and 4 million red cells. The color indices are grouped around 1.1

FIG 1. HEMOGLOBIN RED CELLS AND COLOR INDEX IN 141 DETERMINATIONS IN 75 CASES OF INFECTIVE SUBACUTE AND CHRONIC ATROPHY OF THE LIVER

Lines are continuations from a common point representing zero for both hemoglobin and erythrocytes

FIG 2. MEAN DIAMETER OF RED CELLS IN 64 MEASUREMENTS IN 52 CASES OF INFECTIVE SUBACUTE AND CHRONIC ATROPHY OF THE LIVER

In the closely studied cases, the mean diameter of the red blood cells varied from 7.64μ to 9.0μ . From the other material we collected 64 measurements in 52 patients, there was about the same variation. The values are given in table 2 and figure 2.

It will be seen that over 50 per cent lie above $8\ \mu$. With the same technic, Gram⁸ found values fluctuating between $7.7\ \mu$ and $8.0\ \mu$ in normal persons. Jørgensen and Warburg¹¹ found roughly corresponding limits. In our laboratory also, the normal values found are almost identical with those of Gram. On the basis of these facts it can be asserted that there is a very decided tendency towards an increase in the mean diameter of the red cells in patients suffering from subacute or chronic atrophy of the liver, in No. 23 it reached as much as $9\ \mu$.

TABLE 2.—Mean Diameter of Red Blood Cells in 64 Measurements in 52 Patients

μ Number	7	7-7.5	7.5-8	8-8.5	8.5-9
	1	2	35	23	13

FIG. 3. MEAN DIAMETER PLOTTED AGAINST ICTERIC INDEX

In figure 3, the mean diameter is plotted against the icteric index. It will be observed that there is no correlation between the two.

In figure 4, the mean diameter is plotted against the number of red cells. There is no correlation between the mean diameter and the degree of anemia.

In figure 5, the mean diameter is plotted against the color index. Again no correlation can be detected.

The number of white blood corpuscles varied between 1700 and 12700 in 119 counts in 81 patients (table 3 and figure 6). The last value was quite an isolated one. There was a distinct tendency to low counts, over 50 per cent of them being under 4000. Unfortunately, differential counts were done in only a few cases, but as far as they went no definite deviation from the normal was found.

FIG 4 MEAN DIAMETER PLOTTED AGAINST RED CELLS

FIG 5 MEAN DIAMETER PLOTTED AGAINST COLOR INDEX

The blood platelets were counted in only a few of the cases. There appeared to be tendency towards low values.

The bone marrow The results of the sternal punctures are given in table 4 As a basis for comparison, the normal values found by Gormsen⁷ in a material of 50 normal adults are given in the first column

A comparison with the normal values indicates that in the neutrophile granular cell series there were no changes, no shift to the left, no myeloid hyperplasia and no eosinophilia Hemocytoblasts, lymphocytes, megakaryocytes and reticulum cells exhibited normal appearances, but there were certain abnormalities in the erythroblasts and plasma cells

Four patients had over 30 per cent erythroblasts, 8 patients had from 22 to 26 per cent, while the remaining 12, therefore half the patients, had below 20 per cent

TABLE 3 —Number of Leukocytes in 129 Counts in 81 Patients

Leukocytes	1000—2000	2000—3000	3000—4000	4000—5000	5000—6000	6000—7000	7000—8000	8000—9000	9000
Number	3	25	44	24	23	4	4	1	1

FIG 6 NUMBER OF WHITE CELLS IN 129 COUNTS IN 81 CASES OF INFECTIVE SUBACUTE AND CHRONIC ATROPHY OF THE LIVER

In none was the number of erythroblasts found to be lowered In one patient only (No 22) was there a shift to the left an the erythroblasts, but it was very pronounced No definite macrocytosis of the erythroblasts could be detected in any of the cases Micrometric investigations of the size of the erythroblasts, which normally vary considerably, were not undertaken Megaloblasts were not observed in any of the cases

With regard to the plasma cells, they were 4 per cent in 3 patients, 3 per cent in 6 and below 3 per cent in the other 15, that is to say, in 9 of the patients there was a slight increase in the plasma cells, since the maximal value of 3 per cent for the normal number of plasma cells is very high

Microscopic sections of the bone marrow in 8 patients (Nos 1, 2, 3, 8, 11, 12, 17, 18) showed slight to moderate hyperplasia of the marrow, but in the others the cell content was normal The hyperplasia seemed to depend in part on a striking increase in the erythroblasts, and also on a slight augmentation of all the other cell

forms, so that the state of the marrow seemed to point to a slight increase in the functioning of the bone marrow with greatest emphasis on erythropoiesis

COMMENT

In the blood examinations, i.e., determination of Hb per cent, R B C, color index and direct microscopy, no changes such as those found in pernicious ane

were observed. In conformity with this no sign of megaloblastic transformation of the red bone marrow was seen in any of the bone marrow punctures. We have in some cases attempted to influence the anemia by liver injections, but there was no reticulocyte reaction and no rise in the number of red blood cells.

On the other hand, a marked tendency to an increase in the mean diameter of the red blood cells was observed, which in a few cases assumed very high proportions. Gram,⁸ in 1883, in his measurements of the diameter of the red cells in various diseases demonstrated that the mean diameter in 'ikterus catarrhalis,' that is, hepatitis, is increased. Determined in their own serum, the values lay between $8\ \mu$ and $8.5\ \mu$, in one case with cirrhotic changes it was $8.9\ \mu$. This finding was later confirmed by others¹¹⁻¹⁴ using the same method. The increase in the mean diameter in such cases of liver disease has been attributed to changes in the plasma, possibly to the presence of the salts of bile acids. The fact that in our bone marrow investigations only doubtful macrocytosis of the erythroblasts was demonstrated, and at all events no megaloblastic change in the bone marrow, seems to support the theory that the macrocytosis may at least partly be due to a change in the plasma with consequent swelling of the blood corpuscles. Since there is no correlation between the degree of jaundice and the increase in the mean diameter, the latter cannot depend upon the bilirubinemia but must be caused by other substances in the plasma (bile acid salts?). The question needs a more elaborate investigation.

The tendency to an increase in the plasma cells of the bone marrow must undoubtedly be connected with the plasma protein changes causing the positive Takata reaction, which are characterized by an alteration in the albumin/globulin ratio, decrease in the albumin fraction and increase in the globulin fraction.

CONCLUSIONS

In the observed cases of subacute and chronic infectious atrophy of the liver, of the special type which occurs at the present time in Denmark, a moderate degree of anemia of a hypochromic, normochromic or hyperchromic type was found in the majority of the cases. The color index showed a fairly uniform distribution around the normal value 1.1. There was nothing in the blood picture that resembled true pernicious anemia.

Measurements of red blood cells in their own serum revealed an increase in the mean diameter, often considerable, in over half the cases.

The blood picture with respect to the white corpuscles showed a pronounced tendency in the direction of leukopenia.

In some of the cases, sternal punctures showed the presence of a more or less advanced erythroblastosis, but no really definite macrocytosis of the erythroblasts was observed, and megaloblastic erythropoiesis occurred in none of the cases. A slight increase in the plasma cells was seen in some cases. Sections of the bone marrow, in a number of cases, showed moderate hyperplasia of the marrow.

In no case, either in the blood or bone marrow, could changes be demonstrated which would suggest nonstorage of the material necessary for the maturation of the red blood cells. The increase in the mean diameter of the red blood cells measured in their own serum, which was observed in some cases, is not due to megaloblastic transformation.

blastic erythropoiesis, but possibly to the serum content in substances which affect the osmotic condition of the blood corpuscles

The plasma cell increase in the bone marrow that was found in some of the cases, is presumably connected with the hyperglobulinemia which is a very common accompaniment of chronic hepatitis

The blood and bone marrow changes in our patients thus do not seem to differ from the blood and marrow changes hitherto recognized in chronic hepatitis and liver cirrhosis

MYELOFIBROSIS ASSOCIATED WITH TUBERCULOSIS

A REPORT OF FOUR CASES

By HOWARD W. CRAIL, M.D., HOWARD L. ALT, M.D.,
AND WALTER H. NADLER, M.D.

INTRODUCTION AND REVIEW OF THE LITERATURE

MYELOFIBROSIS is a disease in which the normal blood-forming elements of the bone marrow are replaced by fibrous tissue with compensatory extramedullary hemopoiesis arising in other organs of the reticulo-endothelial system. Clinically, it is characterized by pains in the long bones, back or abdomen, progressive weakness, pallor and subsequent loss of weight. The spleen, liver and sometimes the lymph nodes become enlarged and a refractory anemia of the myelophthisic type develops. Immature leukocytes with or without an increase in total count and frequently the platelet count is either decreased or increased. Bone marrow studies show hypoplasia, usually an increase in the megakaryocytes and eventually, fibrosis. The onset of the disease is insidious and it may last from a few months to years, depending upon the degree of compensation, but the eventual outcome is fatal.

Myelofibrosis was first described by Heuck¹ in 1879, and since that time approximately 100 cases have been reported in the literature under a great variety of titles, the most common of these are "leuco-erythroblastic anemia,"² "chronic non-leukemic myelosis"³ and "myelofibrosis associated with a leukemoid blood picture."⁴ The name "myelofibrosis" was first applied to this disease in 1937 by Mettler and Rusk.⁴ In 1944, Erf and Herbut⁵ contributed materially to this subject by their extensive review of the literature and classification of myelofibrosis as either a primary disease or a disease secondary to such conditions as benzene or fluorine poisoning, irradiation and malignant extension. No mention is made of the possible etiologic role of tuberculosis, although such a relationship had been previously suggested. Among 91 cases of myelofibrosis reported in the literature, there were 7 cases with definite evidence of active tuberculosis. A summary of the findings in the 7 cases is recorded in table 1. The first American to report a case of myelofibrosis was Donhauser⁶ (case A) in 1908. His case was found to have an active tuberculosis involving the mesenteric lymph nodes and he proposed a toxic etiology for the primary marrow disease. One of the 5 cases reported by Dyke⁷ (case B) in 1924 had military tuberculosis, the remaining 4 had other bacterial diseases with bone marrow involvement, and he suggested a disseminated bacteremia as an etiologic factor in this disease. Krasso and Nothnagel⁸ (case C) in 1925 found atypical tuberculous lesions in their case which they believed were caused by avian tubercu-

losis Emile-Weil, Chevallier and Sec⁹ (case D) in 1933 proposed the possibility of a tuberculous etiology for this disease, and in 1935 Hugonot and Sohier¹⁰ reported a case (case E) of myelofibrosis associated with tuberculosis and agreed with this etiologic relationship. Stone and Woodman¹¹ (case F) in 1938 reported a case of myelofibrosis with tuberculosis. They point out the frequency in which tuberculous lesions are found in diseases of the reticulo-endothelial system. Carpenter and Flory¹² in 1941 concluded that the tuberculosis in their case (case G) was a coincidental terminal disease.

The purpose of this paper is to review in detail the clinical picture and autopsy findings of 4 cases of myelofibrosis associated with generalized tuberculosis and to discuss the pathogenesis, diagnosis and treatment of this syndrome. We have observed 5 cases with idiopathic myelofibrosis which will not be reviewed in detail.

TABLE 1—Summary of Cases from the Literature of Myelofibrosis Associated with Tuberculosis

History			Physical Findings				Laboratory Examination			Clinical Course	Autopsy				
Case	Age, Sex	Weight loss	Fever	Splenomegaly	Hepatomegaly	Lymphadenopathy	Anemia	Leukemoid reaction	Thrombocytes	Duration of illness	Tuberculosis		Extramedullary hemopoiesis	Marrow fibrosis	Fibrosis of other organs

in this communication but serve for general comparison with the tuberculous group.

REPORT OF CASES OF MYELOFIBROSIS ASSOCIATED WITH TUBERCULOSIS*

CASE I

C B, a 39 year old housewife, was admitted to the hospital June 7, 1941, complaining of pallor, weakness, dizziness, a skin rash and fever.

Family history Irrelevant.

Past history Amenorrhea had been present for nine years. She had pneumonia at 36 years of age and again at 38. She was occasionally mildly jaundiced and bruised very easily during the last few years.

Present illness The pallor, weakness, and dizziness had been present for the previous thirteen years accompanying episodes of unexplained anemia. These episodes recurred with increasing frequency and persisted during the previous eighteen months. There was no bleeding from any of the orifices. She failed

* Only contributory clinical and pathologic findings are described.

to respond to either liver or iron and received whole blood several times. Following a splenectomy and subsequent phlebitis, she had a daily afternoon temperature elevation, occasionally reaching 101 F. The skin rash started on the left leg three weeks before hospital entry, it then extended to the right leg and both arms. The rash was maculopapular at first, later indurated and finally tender.

Physical examination The pulse was 110 per minute, blood pressure, 116/76, respirations, 24 per minute, temperature, 101.6 F, and weight, 99 pounds. She appeared somewhat emaciated and chronically ill. Over the hands, elbows, and knees the skin had a dusky appearance. An eruption over the legs and arms varied from small, red maculopapules to reddish purple, eczematoid, tender, indurated, nodular lesions distributed mainly over the extensor surfaces. The sclerae were white and the mucous membranes pale. There were a few small cervical, axillary and inguinal lymph nodes palpable. Occasional coarse rales were heard over the base of the left lung posteriorly, with slight dullness in this same region upon perc-

cussion. There was a tachycardia and a coarse systolic murmur was audible over the entire precordial region. The abdomen was soft and not tender, the liver was not palpable.

Laboratory examination The urinalysis showed no sugar and a trace of albumin. The sediment contained 3-5 erythrocytes per high power field and on one occasion hyalin and granular casts. The Wassermann and Kahn tests were negative. A fractional gastric analysis showed 48 units of free HCl and 70 units of total acid. The BMR was plus 6 per cent. The Van den Berg test was 0.8 mg. per cent and the icterus index was 9 units. Other blood chemistry studies were normal. A total of ten stool examinations for blood were found negative. Agglutination tests for typhoid, paratyphoid, dysentery and brucella were negative. Sputum cultures revealed no acid-fast bacilli but many gram-positive diplococci. Blood cultures and fecal cultures were negative. X-ray examination of the chest was normal on 6/7/41, but one week later there was evidence of fluid at the base of the left lung. Hematologic studies (table 2) showed a pronounced normocytic, normochromic anemia with numerous nucleated erythrocytes and a few immature granulocytes in the peripheral blood. There was a moderate variation in the size and shape of the erythrocytes. The reticulocyte count was 1.3 per cent and the platelets were reduced to the lower limit of normal. The bone marrow (table 3) was hypoplastic and revealed a maturation arrest of the erythrocytic series and an increase in the number of megakaryocytes. The red cell fragility test

was normal on two occasions. The spleen, surgically removed on 8/28/40, was reported essentially normal. A skin biopsy of a nodule from the left arm on 6/10/41 was diagnosed as possible erythema nodosum. Acid fast organisms were found in sections made from paraffin blocks containing sediment from pleural fluid. A guinea pig inoculated with pleural fluid was found to have epithelioid tubercles of the lungs, liver and spleen.

Clinical course. The patient had a very stormy course throughout her hospital stay with spiking daily afternoon temperature elevations, sometimes to 106 F, preceded by chills. She became dyspneic, irrational and very restless and expired on 7/3/41.

Necropsy

Thoracic cavity. The left pleural cavity contained 1000 cc of bright red fluid. Both lung bases were adherent to the diaphragm and mediastinum by firm fibrous adhesions. The pleural surfaces were studded with pin-head sized grey, raised tubercles. Microscopically, the alveoli in the left lung base were filled with a fibrinous exudate. The tiny tubercles showed a central necrosis with almost no surrounding cellular reaction.

Heart. The greater vessels and epicardium were covered with the same tiny tubercles seen on the lungs. Histologic study showed an occasional necrotic focus in the myocardium.

Liver. The liver was enlarged and an occasional tubercle was seen on the capsule and cut surface. The sections showed thickening of the capsule with increased intercellular connective tissue. Numerous tiny areas of necrosis were seen in the parenchyma and each was surrounded by a zone of immature blood cells. A few small foci of extramedullary hemopoiesis containing occasional megakaryocytes were seen.

Pancreas. Grossly, the pancreas appeared normal but microscopic studies revealed pronounced interacinar fibrosis and numerous small necrotic tubercles, a few of which were surrounded by immature blood cells.

Lymph nodes. The hilar, retroperitoneal and abdominal lymph nodes were all grossly enlarged. Many showed discrete pin head sized, grey tubercles on their cut surfaces. Microscopically the normal architecture of the glands was completely destroyed and replaced by proliferating granular atypical fibrous tissue occasionally surrounding small foci of extramedullary hemopoiesis. A few hyperchromatic, multi nucleated cells resembling megakaryocytes were seen. Many of the tubercles showed small foci of tuberculous necrosis and a rare Langhans giant cell.

Bone marrow. The marrow from the sternum and vertebrae appeared dark red and dry. Histologically the sections showed a fibrous tissue replacement of the marrow cavity leaving only a few hemopoietic tissue and no fat. The megakaryocytes were increased in number.

to respond to either liver or iron and received whole blood several times. Following a splenectomy and subsequent phlebitis, she had a daily afternoon temperature elevation, occasionally reaching 101 F. The skin rash started on the left leg three weeks before hospital entry, it then extended to the right leg and both arms. The rash was maculopapular at first, later indurated and finally tender.

Physical examination The pulse was 110 per minute, blood pressure, 116/76, respirations, 24 per minute, temperature, 101.6 F, and weight, 99 pounds. Heart The greater vessels and epicardium were covered with the same tiny tubercles seen on the lungs. Histologic study showed an occasional necrotic focus in the myocardium.

Liver The liver was enlarged and an occasional tubercle was seen on the capsule and cut surface. The sections showed thickening of the capsule with increased intercellular connective tissue. Numerous tiny areas of necrosis were seen in the parenchyma and each was surrounded by a zone of immature blood cells. A few small foci of extramedullary hemopoiesis containing occasional megakaryocytes were seen.

Pancreas Grossly, the pancreas appeared normal but microscopic studies revealed pronounced interacinar fibrosis and numerous small necrotic tubercles, a few of which were surrounded by immature blood cells.

Lymph nodes The hilar, retroperitoneal and abdominal lymph nodes were all grossly enlarged. Many showed discrete pin-head sized, grey tubercles on their cut surfaces. Microscopically the normal architecture of the glands was completely destroyed and replaced by proliferating granulomatous, fibrous tissue occasionally surrounding small foci of extramedullary hemopoiesis. A few hyperchromatic, multi-nucleated cells resembling megakaryocytes were seen. Many of the sections showed small foci of tuberculous necrosis and a rare Langhan giant cell.

Bone marrow The marrow from the sternum and vertebrae appeared dark red and dry. Histologically, the sections showed a fibrous tissue replacement of the marrow cavity, leaving small islands of hemopoietic tissue and no fat. The megakaryocytes were increased in number.

MYELOFIBROSIS ASSOCIATED WITH TUBERCULOSIS

Bacteriologic examination All the sections were stained by the Ziehl-Neelson technic and the necrotic foci found filled with acid-fast organisms

Pathologic diagnosis Generalized miliary tuberculosis, extramedullary hemopoiesis in the liver and lymph nodes, fibrosis of the liver, pancreas and bone marrow

CASE 2

W. M., a 50 year old lawyer, was first admitted to the hospital November 10, 1943, complaining of angular pain, intermittent claudication and pallor

Family history and past history Irrelevant

Present illness For two years the patient had noted viselike pain in his chest upon exertion. During the last thirteen months, shortness of breath came with the chest pain, both were relieved by rest. Simultaneously, he developed cramplike pains in the calf of his left leg, brought on by walking. An electrocardiogram in February 1943 showed no significant change. These symptoms became progressively worse and he subsequently noticed that he was becoming fatigued and pale.

Physical examination The temperature was 99.6 F., blood pressure, 120/60, pulse, 96 per minute, respirations, 18 per minute, and weight 178 pounds. The lymph glands were normal. There was no cardiac abnormality. The lungs were clear except for inspiratory wheezes over both apices. The abdomen was soft, and the liver, spleen and kidneys were not felt.

Laboratory examination The urine was repeatedly negative. The Wassermann and Kahn tests were negative. The total serum showed the lung fields to be clear and the heart shadow less than 10 per cent enlarged. Roentgenologic examination of the gall bladder and digestive tract revealed no pathology. The electrocardiogram showed only a left axis deviation. The BMR was minus 7.5 per cent. Repeated blood cultures, stool cultures for enteric pathogens, agglutination tests for typhoid, paratyphoid, and a brucella skin test were all negative. The blood studies (table 2) revealed a moderate normochromic, normocytic anemia with immature leukocytes and normoblasts in the peripheral blood. The reticulocyte count was normal and the platelets were slightly decreased in number. The sternal marrow (table 3) showed an initial hyperplasia with increased erythropoietic activity followed by a marked hypoplasia with an increase in megakaryocytes.

Clinical course Seven days after entry into the hospital the patient was seized with excruciating precordial and epigastric pain with tenderness over the gall bladder, all of which disappeared two days later. During this stay, he had a slight fever for the first two days, again on the seventh day and again on the tenth, eleventh, and twelfth days. He was discharged November 27. He was next seen December 14 as an outpatient complaining of increased weakness and had a decline in the erythrocyte count. He was readmitted to the hospital December 29 for two days and given 400 cc. of whole blood. He continued under ambulatory care without response and was readmitted to the hospital on February 2, 1944. There was no fever at this time. A slight systolic murmur was heard over the apex of the heart. The lungs were normal. The liver was normal in size and the spleen was felt for the first time, extending two finger breadths below the left costal margin. There was a slight generalized lymphadenopathy. He was given two transfusions of 500 cc. of whole blood each and discharged after twenty-four hours. On February 17, while the patient was ambulatory, the spleen was found to be the same size. The liver was now found three finger breadths below the right costal margin and the anemia continued to progress. His last hospital entry was February 23. In addition to previous complaints, he had painful defecation and gross blood in the stools for ten days. His temperature on admission was 100.6 F., pulse, 68 per minute, respirations, 20 per minute, and weight, 164 pounds (a loss of 14 pounds since his first admission). The liver and spleen were palpable as previously noted. A proctoscopic examination was done under caudal anesthesia and a diagnosis of ulcerative proctitis was made. Four days later, an indurated region just outside the sphincter ruptured and spontaneously drained mucopurulent material. He was given numerous transfusions of whole blood for profound anemia but failed to maintain a satisfactory hemoglobin and red cell count level. The sternal puncture (table 3) on February 28 showed a pronounced hypoplasia of the marrow with a marked increase in the number of megakaryocytes. The temperature rose daily to over 100 F., and after the seventeenth hospital day, and the patient expired two days later, April 2, 1944.

Necropsy

Lungs Neither gross nor microscopic milary nodules were described. The sections showed emphysema and focal hemorrhages surrounded by a few hyperchromatic multi-nucleated cells. Pleural thickening was also seen.

Mediastinum A firm nodular mass measuring 6 by 3 by 2 cm. was found in the right mediastinum lying just behind the superior vena cava, superior to the root of the right lung and lateral to the arch of the aorta. This mass cut with ease revealing a bulging, pinkish surface. Several grey green 1-2 cm. in diameter were seen on the cut surface and several small cystic structures contained purulent material. Microscopic studies of this mass revealed confluent lymph nodes almost completely replaced by granulomatous tissue. There were central zones of caseation and necrosis surrounded with varying numbers of epithelioid cells and lymphocytes, all of which were encased in a fibrous tissue. A few multinucleated cells similar to those described in the lung were seen. No Langhans-type cells were present. Several large nerve bundles coursed through the dense fibrous tissue.

Abdominal cavity Firm fibrous adhesions were found about the gall bladder and the upper portion of the colon.

Liver The liver was enlarged (2900 Gm.) and small yellowish nodules were seen beneath the capsule and on the cut surface. Histologic examination showed the sinusoids distended and filled with blood. A fibrous tissue and lymphocytic infiltration was noted about the portal triad. Small nodular foci were seen surrounded by a few epithelioid cells, lymphocytes, and plasma cells. An occasional megakaryocyte was seen. Pronounced fibrous tissue infiltration and hyalinization in the regions adjacent to these atypical tubercles were constant findings.

Spleen The spleen weighed 550 Gm. and several small nodules were palpated beneath the capsule. Microscopically, small foci of caseous necrosis were surrounded by a few round cells. In one of these a single Langhans-type giant cell was seen. The sinusoids were distended and filled with blood and pigment. Small lymph follicles remained. Throughout the pulp, numerous large cells with large oval or indented, hyperchromatic nuclei were found. Many resembled megakaryocytes. Hemopoiesis was not pronounced but the number of immature myeloid cells indicated the presence of this function. The capsule was thickened.

Adrenals The gross features of this organ were not unusual but microscopically both the medullary and cortical layers showed focal necrosis and rather extensive dense fibrous tissue replacement and hyalinization.

Gastro-intestinal tract The only finding of significance in the gastro-intestinal tract was a nodular mass 2 cm. above the pectinate line in the rectum. The mass was produced by a thickening of the wall of the gut but the mucosa appeared intact over the area. Microscopically, the wall was found to be almost completely destroyed by a necrotic process which had begun to include the mucosa as well. Numerous inflammatory cells were seen at the border of this lesion. Many bacteria were seen but no acid fast organisms were demonstrated.

Lymph nodes The lymph glands throughout the body were enlarged and firm. The histologic study revealed a complete destruction of the normal architecture. The capsule was thickened and the stroma increased. The sinusoids were dilated and contained cells. Extramedullary hemopoiesis was seen and a few megakaryocytes were present. Lymphocytes in various stages of development were noted.

Bone marrow Specimens were taken from the sternum, ribs, and vertebrae and all had a dry appearance. The histologic changes included complete alteration of the normal architecture. The marrow was hyperemic and there was a great increase in the number of megakaryocytes. Eosinophilic debris and young fibrous tissue were replacing the normal marrow elements and isolated islands or pockets of myeloid activity were seen. One of the rib sections showed an area of necrosis and increase in the number of small lymphocytes.

Bacteriologic examination All the sections were stained by the Ziehl-Neelson technic and the caseous foci found filled with acid fast organisms.

Pathologic diagnosis Caseous tuberculoma of the mediastinum, milary tuberculosis involving the liver, spleen and bone marrow, extramedullary hemopoiesis in the spleen and lymph nodes, fibrosis of the bone marrow, pleura, liver, spleen and lymph nodes, phlegmonous proctitis.

MYELOFIBROSIS ASSOCIATED WITH TUBERCULOSIS

CASE 3

W. D., a 29 year old male, entered the hospital on January 2, 1946, complaining of weakness, backache, intermittent chills and fever with associated nausea and vomiting.

Family history Irrelevant

Past history Between 1936 and 1937 the patient was employed by General Electric X-ray Corporation and was exposed to considerable x ray radiation and phenol. His leukocyte count at that time was 6,750. In December, 1943, he had a soft mass 6 cm. in diameter in the lower left side of the neck with two lymph nodes palpable below this. Aspiration of the mass was unsuccessful but it disappeared after five x ray treatments with a total of 750 r. He served a tour of military duty in the United States without illness and was discharged in March, 1945.

Present illness His weakness, backache, and a temperature of 99 F. were first noticed in April, nine months before admission. In July, the patient had chills and fever rising to 103 F. which lasted for about an hour and recurred every four to eight hours for eight days. He remained symptom free for three weeks when he had a similar attack also lasting eight days. In early October, he had a third bout. For three months he remained free from chills and fever but was weak. On December 31 he had still another attack. On each occasion nausea and vomiting appeared at the height of the febrile episodes. During this entire period, the patient had a weight loss of 25 pounds.

Physical examination The temperature was 100.4 F., pulse, 90 per minute, blood pressure, 110/70, and weight 128½ pounds. The heart and lungs were normal. The lymph glands and spleen were not palpable. The liver was felt one fingerbreadth below the right costal margin.

Laboratory examination Previous to entry, studies included tuberculin and brucella agglutination studies for the enteric pathogens and brucella, the Davidsohn heterophile agglutination test, x ray of the lumbosacral spine, retrograde and intravenous urograms, and fluoroscopic examination of the chest and gastro intestinal tract. All of these were negative with the exception of a small gastric ulcer demonstrated by fluoroscopy. Proctoscopic and cystoscopic examinations were negative. During hospitalization, the urine had a specific gravity of 1.010, albumin one plus, sugar negative, 20-40 erythrocytes and occasional leukocytes per high power field. Direct and bacterial examinations of the stools were negative. A guinea pig inoculated with urine did not reveal any evidence of tuberculosis. The Wassermann and Kahn tests were negative. The cephalin flocculation test was two plus in twenty four hours and four plus in forty-eight hours. The chest x-rays repeatedly showed a few clean-cut calcified deposits on the left side radiating from the lung root outward. The last film was made about two months before death. The tuberculin skin test was again negative and the electrocardiogram was normal. The prothrombin time was 56.4 per cent of normal, the bromsulfalein showed 12 per cent retention of dye, total protein 6.28 to 3.88 Gm., albumin 3.94 to 2.15 Gm., globulin 2.34 to 1.73 Gm., icterus index 5 units and blood urea nitrogen 12.7 mg. The peripheral blood studies (table 2) showed a slowly progressive normocytic, normochromic anemia, and leukopenia. A few normoblasts and immature leukocytes were seen. The reticulocyte count was 1.8 per cent and the platelets were normal. Aspirated sternal marrow (table 3) showed hyperplasia at first, followed later by a distinct hypoplasia with an increase in megakaryocytes. No malarial parasites were found. Biopsy studies of the sternal bone marrow (fig. 2) in July revealed complete alteration of the normal architecture. These normal cellular elements were greatly reduced and widely scattered. No fatty tissue and eosinophilic debris. Biopsy material from a retroperitoneal mass at the same time was composed of large epithelioid cells with pale vesicular cytoplasm. Scattered throughout these cells was a fine network of fibrous connective tissue with new-growing fibroblasts and diffuse, small, round-cell infiltrations more dense in some areas than others. A few polymorphonuclear cells and an occasional large multi-nucleated cell with characteristics of a Dorothy Reed cell were seen. The diagnosis was an inflammatory process with many characteristics of Hodgkin's disease. Sections of the liver were essentially normal.

Clinical course The patient was discharged January 13 on his fourth afebrile day, only to be readmitted to the hospital January 23 with a recurrence of the backache and weakness followed by chills, fever, nausea and vomiting. Fine, moist, inspiratory rales were heard throughout the chest and a soft systolic murmur was audible over the tricuspid area. The liver was four fingerbreadths below the right costal margin and the spleen could be palpated subcostally. There was no adenopathy. His fever subsided March 7 and he was discharged ten days later. On March 26 the patient was readmitted with another attack.

but this time with a severe cough and pain and tenderness in the right flank. The liver and spleen were palpable as before and there was some question of a palpable mass in the region of the right kidney. The fever reached 103 F on the second day but subsided rapidly and the patient was discharged April 1. Twenty days later the patient made his last entry into the hospital. He weighed 123 pounds. The liver was palpable four fingerbreadths below the right costal margin and was tender. The spleen was again palpable. During this admission, biopsies were taken from the sternal marrow (*see Laboratory Examinations*). On July 3 a laparotomy was done and enlarged retroperitoneal tumor masses grossly resembling Hodgkin's disease or lymphosarcoma were seen. Biopsies were taken of these and also of the liver (*Laboratory Examinations*). Eight x-ray treatments were given over the abdominal mass with no improvement. His temperature ran a very septic course, going to 104 F, and showed daily and almost hourly fluctuations. He continued to lose weight and became progressively worse and on August 19 died. Before death, his peripheral blood picture revealed marked pancytopenia. His spleen and liver were

FIG 1 Liver from W D showing large areas of fibrosis

in size and edema became pronounced. Treatment throughout his illness included sulfonamides, penicillin, oral streptomycin (for seven days), atabrine, quinine, plasmoquin, emetine, salicylates, the x-ray treatment mentioned above, and four blood transfusions. None of these had any effect on the course of the disease.

Necropsy

Thoracic cavity Both thoracic cavities contained about 1200 cc of a clear yellow fluid.

Lungs The lungs were adherent to the parietal pleura by a few firm fibrous adhesions and their surfaces were covered with greyish-white raised nodules ranging from pin-head size to 0.2 cm in diameter. The cut surfaces were wet and the same nodules were seen. The microscopic appearance of the lung was that of a multitude of tiny anemic infarcts in all the sections. The centers of these foci were caseous but there was almost a complete absence of the peripheral cellular reaction so common in tuberculosis. No Langhans giant cells were observed. Many of the surrounding alveoli contained cellular debris and fibrin resembling the consolidation of pneumonia. The pleura was thickened.

Abdominal cavity The abdominal cavity was filled with clear yellowish fluid. There was a large, nodular, perivertebral, retroperitoneal mass in the epigastric region.

Liver The liver was enlarged (1650 Gm). The surface was speckled with pin-head sized, subcapsular, greyish-white nodules, a few larger yellowish nodules and firm white irregular patches.

1) The cut surface was similar except that the firm white areas were very tough and extended deeply into the parenchyma mainly about the larger vessels. Histologic examination revealed a thickened capsule and distention of the sinuses with blood. Scattered throughout the parenchyma were a multitude of tiny tubercles. Many of these contained one or two typical Langhan giant cells. A few were surrounded by the typical cellular reaction seen in tuberculosis. The large white plaques described at autopsy were composed of organized fibrous and hyalinized connective tissue and at the borders the connective tissue extended into the parenchyma, leaving islands of liver cells behind. Foci of lymphocytes were scattered throughout this fibrous tissue. An occasional megakaryocyte and a few small foci of extramedullary hemopoiesis were seen.

Spleen The spleen was enlarged (700 Gm) and a small accessory spleen was found. Numerous small greyish-white nodules were seen beneath the capsule and on the cut surface. Firm, white, irregular plaques on the cut surface were similar to those seen in the liver. The sections showed a thickened fibrous capsule. The sinusoids were distended with blood. The lymph follicles were completely dispersed and only an occasional small aggregate of lymphocytes could be found about a vessel. Large areas of fibrosis were seen but the most unusual finding was the widespread seeding of small tubercles as seen in the liver. There was little surrounding cellular reaction though occasional Langhan giant cells were found in the tubercles. Immature myeloid and erythroid cells and a moderate number of large cells with large, irregular, dense nuclei resembling megakaryocytes could be seen diffusely scattered throughout the sections.

Pancreas (fig. 3) Microscopic examination revealed an increased amount of connective tissue and several atypical tubercles similar to those previously described.

Adrenals The microscopic section showed an increase in fibrous tissue and numerous small atypical tubercles.

Retroperitoneal lymph nodes The retroperitoneal mass was an irregular, enlarged, adherent group of lymph nodes which when sectioned showed occasional small yellowish foci. Histologic study showed a complete obliteration of the normal architecture with a greatly increased stroma. Much chronic granulomatous tissue was present with a few scattered lymphocytes, an occasional multinuclear Sternberg-Reed type of cell and atypical tubercles. Nerve bundles were seen encased in the fibrous tissue.

Bone marrow (fig. 4) Bone marrow taken from the sternum, ribs and vertebrae showed almost complete obliteration of the marrow cavities by dense fibrous tissue. Only a very few normal myeloid and erythroid foci could be seen. Megakaryocytes were prominent and an occasional atypical tubercle containing acid-fast organisms was found.

Bacteriologic examination All the sections were stained by the Ziehl-Neelson technic, the caseous foci everywhere and the connective tissue of the liver, spleen and lymph nodes were filled with acid fast organisms. These acid-fast organisms were cultured on glycerin-egg media, inoculated into a series of laboratory animals and tested as to streptomycin sensitivity. The organism was proven to be a human type of *M. tuberculosis*, possibly of low virulence and sensitive to streptomycin.

Pathologic diagnosis Diffuse fibrosis of the liver, spleen, lymph nodes, adrenals and bone marrow, with interacinar fibrosis of the pancreas, extramedullary hemopoiesis in the spleen and liver, generalized miliary tuberculosis.

CASE 4

M. B., a 36 year old housewife entered the hospital June 23, 1945, complaining of weakness, night sweats, headache, chest pain and a nonproductive cough.

Family history A sister died from tuberculosis.

Past history Irrelevant.

Present illness The patient was apparently well and healthy until after the normal delivery of a baby October 11, 1944. Two days postpartum an enlarged spleen was found and subsequently a diagnosis of Banti's disease was made. A splenectomy was done November 14, 1944. The pathologic report on the spleen suggested Hodgkin's disease. Following operation the patient gained 35 pounds and resumed her normal duties. In May 1945, her menstrual period lasted twelve days and she passed numerous large clots. At this time she caught cold and her temperature rose to 103 F for a few days. She continued

Fig 2 (upper) Photomicrograph of a sternal marrow biopsy from W D showing infiltrating fibroblastic tissue cells with dispersion of the blood-forming element
 Fig 3 (center) Photomicrograph of the pancreas from W D showing interacinar fibrosis
 Fig 4 (lower) Photomicrograph of the bone marrow from W D at autopsy showing extensive fibrosis with little remaining hemopoietic tissue

to feel ill and began to lose weight. Weakness then became her major complaint and was soon followed by night sweats, a persistent headache, pain in the chest and back and an irritating, nonproductive cough.

Physical examination Her temperature was 100.2 F, pulse, 100 per minute, blood pressure, 130/72, and respirations, 24 per minute. A soft systolic murmur was audible over the base of the heart. The lungs were normal. The liver was enlarged, extending approximately five fingerbreadths below the right costal margin. A moderate generalized lymphadenopathy was noted.

Laboratory examination The urine contained a trace of albumin and 7-10 leukocytes per high power field. The Kahn test was negative and blood chemistry studies, including the icterus index, were all normal. The BMR was plus 20 per cent and the electrocardiogram was normal. X-ray examinations of the chest were repeatedly normal until a few days before death when a diffuse flocculant increase in density was seen involving both lung fields. This was most pronounced at the bases and suggested an acute pulmonary edema. The peripheral blood studies (table 2) showed a predominance of young myeloid cells with a great increase in the number of megakaryocytes. The pathologic sections from the spleen were re-examined and reported suggestive of myelogenous leukemia.

Clinical course The treatment consisted of repeated blood transfusions. The patient grew progressively weaker and continued to lose weight. Her temperature was high, the peaks ranging between 104 F and 105 F and there was delirium. In the last week of her life, ascites and jaundice were present. She died September 21, 1945.

Necropsy

Thoracic cavity Both pleural cavities were obliterated by firm adhesions between the visceral and parietal pleurae.

Lungs The pleural and cut surfaces of the lungs were studded with numerous small greyish-white, firm nodules varying in size from 0.1 to 0.5 cm. On microscopic study, tiny areas of focal necrosis were surrounded by a zone of immature blood cells and phagocytes. Foci of extramedullary hemopoiesis and numerous megakaryocytes were seen.

Abdominal cavity Five hundred centimeters of dark, straw-colored fluid were found in the abdominal cavity. The visceral and parietal peritoneum was studded with small greyish-white nodules.

Liver The liver was enlarged (2670 Gm). The capsule and cut surfaces were covered with small tubercles. Histologic study (fig. 5) showed areas of focal necrosis and infarction surrounded by zones of hemopoiesis. The liver cords were small and surrounded by hyalinized connective tissue which obliterated many of the sinuses. Foci of extramedullary hemopoiesis and megakaryocytes were seen.

Pancreas Microscopically, there was a pronounced periductile, perivascular and periglandular fibrosis.

Adrenals The sections showed fibrous tissue replacement with separation of the cortical and medullary cells and microscopic areas of caseation and foci of extramedullary hemopoiesis.

Bone marrow The cortices of the ribs, sternum, and vertebra were thickened and the trabeculae prominent. The medullary spaces were filled with a dry, fibrous-like tissue. Microscopically, the normal marrow was completely distorted (fig. 6). Relatively few hemopoietic cells remained and these were widely dispersed through the connective tissue filling the marrow spaces. The megakaryocytes appeared increased in number. Necrotic foci were also found.

Lymph nodes The mediastinal, retroperitoneal and perivertebral lymph nodes were enlarged and matted together. Microscopic study of these lymph nodes showed proliferating connective tissue infiltrated with immature blood cells and a few megakaryocytes. Many of the nodes contained focal areas of necrosis.

Bacteriologic examination All of the sections were stained by the Ziehl-Neelsen technic and huge numbers of acid fast organisms were found in the areas of necrosis in all the organs.

Pathologic diagnosis Extramedullary hemopoiesis in the liver, lung, spleen and lymph nodes, extensive fibrosis of the liver, spleen, pancreas, adrenals, lymph nodes and bone marrow, generalized acute, diffuse, miliary tuberculosis.

ANALYSIS OF CASES

A summary of the clinical, hematologic and pathologic data of the four cases of myelofibrosis with tuberculosis is recorded in tables 2, 3 and 4. We studied W. M., W. D. and M. B. during life and the records of C. B. several years after death. M.

Fig 5 (upper) Photomicrograph of the liver from M B showing miliary tubercle with associated fibrosis and hyalinization
Fig 6 (lower) Photomicrograph of the vertebral bone marrow from M B at autopsy showing extensive myelofibrosis

B has been reported¹² previously but is included to make the present study more complete. The diagnosis of tuberculosis was made antemortem in C B and was considered but not established in W D.
History The primary complaints of these cases were pain in the long bones, back

or abdomen, fatigue, progressive weakness, pallor and loss of weight. Their *ages* ranged between 29 and 50, averaging $33\frac{1}{2}$ years. The *sex distribution* was equal. A definite *history of a tuberculous* contact was obtained in M. B. W. D. gave a history of cervical adenopathy which was suggestive of tuberculosis.

Physical findings. All of the patients showed a daily afternoon *fever* with occasional spikes to 104 F. During the last few months, the daily elevations frequently went above this mark. W. D. had repeated recurrences of chills and fever, sometimes two or three a day with afebrile remissions lasting eight to twenty days. The *spleen* in each case was moderately enlarged. Splenectomies were done on C. B. and M. B. early in their illnesses with probable adverse effects. The *livers* were markedly enlarged, smooth and nontender in three cases. In C. B., the liver was palpable only on deep inspiration. Generalized *lymphadenopathy* was moderate in all cases. The retroperitoneal lymph nodes were greatly enlarged in W. D. and were palpable through the abdominal wall as a firm, epigastric mass.

Laboratory findings. A refractory *anemia* was present in all cases. The anemia was profound throughout the illness of W. M. and he required frequent transfusions. In the remaining cases, the anemia was slowly progressive but became terminally pronounced. A *leukemoid reaction* characterized by the presence of immature leukocytes and normoblasts occurred in each case. Three cases (C. B., W. M. and W. D.) had a progressive *leukopenia*. On the other hand, M. B. had a leukocyte count above 100,000 and the differential closely resembled an acute myelocytic leukemia. The *platelet* count paralleled the leukocyte count, it was reduced to the lower limits of normal in three cases and was well above 500,000 in M. B. Giant platelets and megakaryocytes were seen in peripheral blood smears of the latter case. In each case, the *reticulocyte count* was normal. The *sternal marrow* aspirations in W. M. and W. D. early revealed a hyperplastic marrow. Later the marrow became hypoplastic and sternal aspirations then resembled the peripheral blood both in total and differential cell counts. The number of megakaryocytes was increased in each case. Single marrow aspirations on the two remaining cases showed hypoplasia with an increase in the megakaryocytes. A bone marrow biopsy was done on only one patient (W. D.). The sections revealed a depletion of the normal hemopoietic tissue and fat with beginning fibroblastic replacement and a marked increase in the megakaryocytes. One patient (W. D.) consistently had a low grade hematuria. *Stool* examinations for blood were repeatedly negative in all instances. Uniform *blood chemistry* studies were not carried out on these patients, however, W. D. and M. B. showed evidence of a slightly decreased liver function. The icterus index was normal in each case. *Bacteriologic* and *serologic studies* were repeatedly negative in all but C. B., where acid-fast organisms were recovered from fluid aspirated from the chest late in the illness. Unfortunately, tuberculin skin tests were made in only one case (W. D.) and were reported negative. *Roentgenologic examinations* of the chest revealed evidence of old, healed tuberculosis in each case. Terminally, pleural effusion was found in C. B. and mottling suggestive of edema in M. B. Since miliary tubercles were found in the lungs at autopsy, serial roentgenograms might have been of diagnostic aid late in the disease.

Clinical course. All patients ran a continued downhill course with progressive

weakness, loss of weight and fever ending in death C B and M B developed terminal jaundice The *duration of illness* ranged from twelve to eighteen months with an average of 16.2 months

Necropsy findings Generalized, caseating, *miliary tuberculosis* was found in all of the organs in these cases These lesions were small but were found filled with large numbers of acid-fast organisms *Extramedullary hemopoiesis* and an increase in *megakaryocytes* were evident in every instance, most commonly in the spleen, lymph nodes and liver The *lymph nodes* in each case were enlarged and the normal cellular elements were replaced by proliferating granulomatous tissue *Bone marrow* from the sternum, rib and vertebra in each case was replaced by varying amounts of connective tissue which was confirmed by special staining * The most massive fibrosis was present in W D where it had progressed extensively since the time of biopsy three months before death (figs 2 and 4) *Fibrosis* and *hyalinization* of organs other than the bone marrow, particularly of the liver, (figs 1 and 5) spleen, pleura, pancreas (fig 3) and adrenals were prominent in all of our cases

Comparison of the Four Tuberculous Cases with Five Cases of Idiopathic Myelofibrosis

We have observed and analyzed 5 cases of idiopathic myelofibrosis (table 4) which will be reported elsewhere Three are still living and 2 have died These patients have many features in common with the tuberculous group, namely the splenomegaly, anemia, leukemoid blood picture, fibrosis in the bone marrow with an increase in megakaryocytes and extramedullary hemopoiesis On the other hand, there were certain differences in the two groups The idiopathic cases were in an older age group (53 to 77 years), there was no fever except terminally in one case, the spleens were larger and lymphadenopathy was less prominent The average duration of illness in this group at the time of writing was thirty-two and one-half months as compared to sixteen months in the tuberculous patients There was no evidence of active tuberculosis in the idiopathic group In general, the idiopathic cases resembled the tuberculous cases hematologically, but the latter group ran a septic course and terminated fatally within a shorter time

DISCUSSION

Pathogenesis The possible role of tuberculosis in the production of myelofibrosis has been considered by previous writers (*see Review of the Literature*) However, there is no clean-cut evidence in favor of this relationship In a preliminary study of this subject, one of us (H W C)¹² proposed that the acid-fast organisms found in the atypical tubercles of M B and in other cases reported in the literature may be responsible for the myelofibrosis Furthermore, since the atypical tubercles in these cases resembled the lesions produced experimentally with avian tuberculosis, it was suggested that the organisms be identified in subsequent investigations This was done in W D where the acid-fast bacilli were obtained at autopsy and identified according to the method described by Feldman¹³ The organism in this case was found to be a human tubercle bacillus, possibly of low virulence and definitely sensitive to streptomycin

* Mallory's connective tissue stain

Acute caseating miliary tuberculosis is the name Rich¹⁴ applied to the atypical disease seen in our cases. He points out this disease may be overlooked at autopsy or, if recognized, may be misinterpreted as avian tuberculosis. Rich¹⁴ has experimentally produced the lesions of caseating tuberculosis by injection of large numbers of bacilli into the blood stream of a hypersensitive animal. They become widely disseminated and are characterized by tiny caseous foci without epithelioid cells, lymphocytes or giant cells, the organisms multiply rapidly in these lesions and large numbers are found at autopsy. If the animals survive, the organisms are reduced and typical tubercles develop. Complete healing may take place with or without scar formation. Pinner¹⁵ believes that this type of reaction is due to an atypical response of the host. Clinically and experimentally, this massive dissemination of organisms is characterized by toxemia and spiking temperature elevations.

The proliferative reactions in tuberculosis have led to widespread investigations. According to Rich,¹⁴ the factors influencing fibrosis are as follows: (1) virulence of the organism, (2) race, (3) presence and degree of immunity or hypersensitivity, and (4) resistance of the host. Sabin¹⁶ studied the tissue response to various fractions of acid-fast organisms. She found that an unsaponified higher alcohol derived from the waxes produced a remarkable proliferation of fibroblasts both diffusely and in small clumps. Kaufmann¹⁷ described a relatively benign form of tuberculosis involving the lymph nodes which he called 'attenuated tuberculosis'. It runs a chronic course with massive enlargement of the glands due to a proliferative reaction. There is little or no caseation. The organisms are often difficult to demonstrate. Pinner¹⁵ describes sarcoidosis as a hematogenous tuberculosis with a productive tissue response and no caseation. He believes this is an expression of a high degree of specific resistance as manifested by the benign course, the absence of tissue destruction and toxic symptoms and the efficient destruction of tubercle bacilli shortly after focalization has taken place. Such a concept embraces a large field of fibrotic and hyalinized lesions resembling tuberculosis. Ewing¹⁸ and L'Esperance¹⁹ have strongly supported the concept of a tuberculous etiology of Hodgkin's disease. Arneith,²⁰ Muller,²¹ Pinner¹⁵ and others²² occasionally observed hematologic findings in miliary tuberculosis similar to those described in our cases. These authors point out that a shift to the left of the granulocytes is one of the heralding features of active, progressive tuberculosis. This may be accompanied by a leukocytosis or a leukopenia. * Leukemoid reactions often accompanied by a leukocytosis and the presence of myeloblasts do occur and are at times difficult to differentiate from leukemia.²³ A low grade or moderate anemia is common in pulmonary tuberculosis. However, Pinner¹⁵ states that marked degrees of anemia (below 75 per cent) are strongly indicative of extrapulmonary involvement or of nontuberculous complications. Marrow studies in miliary tuberculosis have shown early hyperplasia of all the hemopoietic tissue and later hypoplasia or aplasia. Muller,²¹ in some of his cases, describes marrow of generalized tuberculosis, filled with eosinophilic debris.

* Recently, in our clinic, autopsy has been performed on a patient who had miliary tuberculosis associated with a hypoplastic marrow without fibrosis. During life, she had a leukoerythroblastic anemia.

and sometimes connective tissue fibrils with islands of hyperplastic myelopoietic tissue. Further evidence that tuberculosis depresses the marrow is demonstrated by the suppression of leukemia by an active tuberculous infection (Jaffe,²⁴ Heinle and Weir²⁵ and Ulrich and Parks²⁶)

Undoubtedly the atypical miliary tuberculosis seen at autopsy in the cases reported here and in the literature represent a terminal dissemination of the type described by Rich.¹⁴ However, a review of the clinical course, physical findings, hematologic and pathologic examinations coupled with the autopsy findings and bacteriologic studies, strongly suggest a protracted, progressive granulomatous disease of tuberculous origin. The degree and extent of fibrosis of the marrow and other organs may be dependent upon factors previously enumerated and upon the length of life of the patient. The marrow fibrosis in these cases is considered to be part of a generalized disease.

Diagnosis. The possible diagnosis of myelofibrosis must be entertained when a patient complaining of bizarre pain, weakness and weight loss is found to have splenomegaly, hepatomegaly, lymphadenopathy and hematologic findings of refractory anemia with a leukemoid reaction. Tuberculous involvement is to be thought of if there is in addition a recurrent, spiking or persistent unexplained fever.

A sternal aspiration in myelofibrosis reveals a hypocellular marrow with an increase in the megakaryocytes. The tuberculous case frequently shows an initial marrow hyperplasia followed by hypoplasia. This material must be carefully studied for tuberculosis as described by Schleicher.²⁷ A *bone marrow biopsy* must be obtained to confirm the diagnosis of myelofibrosis. Lymph node biopsies and splenic punctures may be of assistance. These tissues should be cultured, inoculated into guinea pigs and examined pathologically for acid-fast organisms. X-ray examination of the chest may reveal evidence of miliary tuberculosis but the absence of findings does not rule out this disease. With the proper diagnostic approach it should be possible to make the diagnosis of myelofibrosis with tuberculosis antemortem in many cases.

Treatment. Blood transfusions temporarily raise the oxygen carrying power of the blood but have no effect on the course of the disease. As is to be expected, there is no response of the anemia to liver and iron, and sulfonamides and penicillin have no effect on the fever. Splenectomy and irradiation are contraindicated as they reduce the compensatory hemopoietic mechanism and probably hasten death. Streptomycin offers the only hope in the treatment of this disease. Recent reports indicate that certain cases of generalized tuberculosis²⁸ and tuberculous meningitis³⁰ are benefited by adequate treatment with streptomycin. When the diagnosis is made, it would seem logical to give 2 to 3 Gm. of streptomycin daily over a prolonged period of time. Since the disease is characterized by spontaneous remissions, one must be guarded in interpreting therapeutic results.

SUMMARY

Myelofibrosis (fibrotic bone marrow and, usually, an increase in megakaryocytes) is characterized by generalized pains, weakness, loss of weight, enlargement of the liver and spleen and a leuko-erythroblastic anemia.

Four cases of myelofibrosis associated with generalized tuberculosis have been reviewed in detail. Autopsy examination of the 4 cases revealed acute, caseating tuberculosis which was considered to be responsible for the bone marrow and generalized fibrosis observed. A similar type of tuberculosis occurred in 7 of 91 cases of myelofibrosis reviewed in the literature. The pathogenesis of myelofibrosis associated with tuberculosis is discussed.

In the diagnosis of this syndrome, attention is called to the importance of obtaining a bone marrow biopsy and making a complete bacteriologic and pathologic study of this tissue for tuberculosis.

The 4 tuberculous cases here reported as compared with 5 cases of idiopathic type, are younger, have hyperpyrexia, less splenic but greater lymph node enlargement and run a shorter course before death.

ACKNOWLEDGMENT

The authors wish to thank Dr. Guy P. Youmans and Mrs. Elizabeth Williston of the Department of Bacteriology, Northwestern University Medical School, for their assistance in the bacteriologic studies, and Dr. Richard H. Young for permission to study and report case 1 (C. B.).

THE OCCURRENCE OF NORMOBLASTS IN THE PERIPHERAL BLOOD IN CONGESTIVE HEART FAILURE AN INDICATION OF UNFAVORABLE PROGNOSIS

By J GROEN, M D , AND E G GODFRIED, M D

DURING THE PAST year the authors have observed 9 patients with severe congestive heart failure, all of whom showed a varying number of normoblasts in the peripheral blood. In some of these cases there was a temporary remission of the sequellae of the heart failure, during this remission the normoblasts disappeared from the peripheral blood. However, in all cases the patients died.

CASE REPORTS

Case 1 C D , a 34 year old woman, was admitted on June 12, 1946, because of decompensated mitral stenosis. She was slightly jaundiced, the liver was greatly enlarged, there were infarcts in both lungs. Five per cent normoblasts were found in the peripheral blood. The patient died on July 2, 1946. The diagnosis was confirmed at autopsy.

Case 2 S W , a 56 year old woman, entered the hospital on May 9, 1946, because of dyspnea, from which she had been suffering during the previous six months. She was cyanotic, dyspneic, and had slight jaundice. On examination, a mitral insufficiency, stenosis and auricular fibrillation were found. The liver was much enlarged, there was extensive edema. During this period, 10 and 17 per cent, respectively, of normoblasts were found on two occasions in the peripheral blood, but these disappeared within three days when her condition improved. In spite of this remission, the patient died on May 22, 1946. On the day before her death she had another infarction of the lung.

On May 13, a sternal puncture had been performed. The bone marrow was found to be essentially normal, but the presence of a relatively great number of normoblasts and erythroblasts was noted (about 25 per cent of all nucleated cells).

The diagnosis of valvular heart disease was confirmed at autopsy, there were many infarcts in both lungs and a thrombosis of the left auricle of the heart.

Case 3 A G , a 20 year old woman, entered the hospital on May 4, 1946, with cardiac decompensation, due to insufficiency and stenosis of the mitral valve. She was dyspneic but not cyanotic. There was no jaundice. The liver was enlarged. There was massive edema of the legs. The blood count was as follows:

	May 6, 1946	May 7, 1946
Leukocytes	12,800	17,000
Erythrocytes	3,640,000	3,900,000
Hemoglobin	61	63
Normoblasts	—	7
Myelocytes	1	0.5
Metamyelocytes	0.5	0.5
Stabs	5.5	9
Polynuclear cells	54.5	69
Eosinophiles	0.5	—
Monocytes	2.5	2.5
Lymphocytes	35.5	18.5

There was a marked anisocytosis, poikilocytosis, polychromasia, anisochromia and macrocytosis. The patient died on May 8, 1946. The autopsy showed a verrucous endocarditis (of the mitral and aortic valves), thrombi in the left auricle of the heart, congestion, fatty degeneration and regeneration of the liver.

Case 4 A B , a 34 year old man, was admitted on June 28, 1946, with a diagnosis of insufficiency and

From the Second Medical Service of the Wilhelmina Gasthuis, Amsterdam, Holland

stenosis of the mitral valve and aortic stenosis. He was cyanotic and extremely dyspneic. There was slight jaundice. The liver was palpable. There was no edema. The patient had distinct anginal pain. An electrocardiogram showed changes that were typical of a severe myocardial lesion. The blood picture was as follows: leukocytes, 7,000, erythrocytes, 5,000,000, hemoglobin, 100, normoblasts, 3, stabs, 4, polynuclear cells, 80, monocytes, 1, lymphocytes, 15.

The patient died on July 5, 1946. No autopsy was performed.

Case 5 H S, a 71 year old man, was admitted on March 4, 1946, with cardiac asthma. He had been known for years to have suffered from hypertension. The patient was extremely cyanotic. There was slight jaundice and very severe dyspnea. He showed all the signs of congestive heart failure. There was extensive edema of the legs, ascites and hydrothorax. One normoblast was found per 100 nucleated cells. When the signs of heart failure disappeared, normoblasts were no longer seen. The patient died November 4, 1946. Autopsy showed hypertrophy of the heart, multiple emboli in both lungs and chronic glomerulonephritis.

Case 6 P H, a 48 year old woman, was admitted on November 9, 1946, with mitral insufficiency and stenosis. She was dyspneic and cyanotic. No jaundice was present. There was gangrene of the tip of the nose and of both lower legs. No pulsations were felt in the left femoral and the right popliteal arteries. There was an infarct in the right lung. The blood count was as follows: leukocytes, 22,000, erythrocytes,

TABLE 1—*Blood Picture of S W (Case 2)*

	5/10	5/11	5/13	5/14	5/16	5/18	5/21
Leukocyte count	12,500			12,700	12,400		26,000
Erythrocyte count	5,250,000				5,360,000		5,310,000
Hemoglobin	77				80		82
Normoblasts	10	17	3				
Myelocytes			1				
Metamyelocytes	1	1					
Stabs	4	7	4	4	4	4	7
Polynuclear cells	82	81	86	88	89	79	84
Monocytes	1	2	1	4	3	1	
Lymphocytes	11	9	8	4	4	16	9

4,020,000, hemoglobin, 59, normoblasts, 1, stabs, 6, polynuclear cells, 80, eosinophiles, 1, monocytes, 3, lymphocytes, 10.

The patient died on November 16, 1946. The autopsy revealed a thrombus in the left auricle of the heart, an infarct of the lower lobe of the right lung, an embolic obturation of the left iliac artery and congestion of the liver.

Case 7 T V, a 45 year old woman, was admitted on November 19, 1946. She had a history of chorea twenty-seven years previously. A diagnosis of mitral insufficiency and stenosis was made. The patient had auricular fibrillation and multiple infarctions of both lungs. There was gangrene of the tip of the nose and of the right foot, the latter was caused by an obturation of the right femoral artery. The patient was extremely dyspneic and deeply cyanotic. There was no jaundice. An electrocardiogram showed bundle branch block. The blood count was as follows: leukocytes, 2,800, erythrocytes, 4,500,000, hemoglobin, 78, normoblasts, 4, myelocytes, 1, metamyelocytes, 1, stabs, 1, polynuclear cells, 78, monocytes, 1, lymphocytes, 14.

The patient died on November 20, 1946. At autopsy the clinical diagnosis was confirmed: valvular heart disease, thrombosis of the right auricle, multiple infarctions in both lungs. A small amount of fluid was found in both pleural cavities. Cardiac cirrhosis of the liver with regeneration was also present.

Case 8 T S, a 40 year old woman, was admitted for the first time on April 24, 1946, because of mitral insufficiency and stenosis, with auricular fibrillation. She had a greatly enlarged liver with ascites. The patient left the hospital on July 6, and was readmitted on August 30. On this second admission she was extremely dyspneic, cyanotic and subicteric. On October 1, a few normoblasts were found in the peripheral blood. The patient died on October 14, 1946. At autopsy, the mitral valve lesions were found,

in addition, she had a tricuspid stenosis and there was a thrombus in the right atrium. The liver was cirrhotic.

Case 9 J. D., a 63 year old woman, was admitted on November 13, 1946, with a diagnosis of mitral insufficiency and stenosis, with auricular fibrillation, and decompensation. She was slightly dyspneic, and deeply cyanotic. There was no jaundice. Infarctions were present in both lungs. The blood count was as follows: leukocytes, 5,600, erythrocytes, 4,300,000, hemoglobin, 88, normoblasts, 2, polynuclear cells, 66, eosinophiles, 2, monocytes, 5, lymphocytes, 27.

The patient died on February 5, 1947. The clinical diagnosis was confirmed at autopsy, there were multiple infarctions in both lungs.

DISCUSSION

The appearance of normoblasts in the blood of patients with congestive heart failure is mentioned only twice in the literature. The standard textbooks of diseases of the blood and of the heart describe the finding of normoblasts in the peripheral blood only in relation to congenital heart disease accompanied by cyanosis. In

TABLE 2a — *Cabot's cases*

Patient	Age	Clinical data	Hematologic data	Remarks
Case I	8	Mitral disease, nephritis	Hb 35, 2% normoblasts, leukocytes 220,000	Died

Case III	30	Mitral disease, aortic insufficiency	1st day Hb 10, 8% normoblasts, leukocytes 6,000 7th day Hb 10, 4% megaloblasts, 7% normoblasts, leukocytes 4,200 15th day Hb 15, leukocytes 10,400 20th day Hb 12.5, 1% megaloblasts, leukocytes 5,000	"

acquired valvular disease, and in other forms of congestive heart failure, this sign seems to have been overlooked by the majority of investigators.

Cabot¹ mentions, in the fifth edition of this book, 'The Clinical Examination of the Blood,' three cases with decompensated mitral disease in which a severe anemia was present. The blood contained nucleated red cells. All three were chronic cases without active endocarditis. He does not give further details, and there are no data regarding the presence of infarcts in the lungs. Two of Cabot's patients died, the fate of the third is not mentioned.

In 1931, Frank and Hartmann² described six patients with various types of 'right-sided heart failure' in whom normoblasts were found in the peripheral blood. All cases showed cyanosis and some degree of jaundice, and all of them died. The cases of Frank and Hartmann were not anemic.

Table 2 summarizes the authors' observations, and some of the data on the cases described by Cabot, and Frank and Hartmann. From this table it is evident that all the cases showed a very severe insufficiency of the heart. It is also clear that it was

of decompensated valvular heart disease as well as cases of heart failure in hypertension or in coronary thrombosis. In Cabot's cases it might be argued that the normoblastosis was a result of the anemia rather than of heart disease, but in all other cases anemia played no role. The predominant factor in these nonanemic cases seemed to be a marked diminution of the oxygenation of the blood in the lungs, as evidenced during life by severe cyanosis. After death this was explained

in many cases by the finding of a thrombus in one of the auricles or ventricles of the heart and/or infarcts of the lungs. Three of Frank and Hartmann's cases had myocardial infarction with secondary formation of a mural thrombus in the left ventricle. One patient had a thrombosis of the right pulmonary artery. Two patients had severe decompensation as a result of mitral stenosis. In all our cases, thrombosis or embolism inside the heart or pulmonary arteries was found, eight times this was verified at autopsy. Apart from thrombi and emboli in the heart and lungs, the postmortem examinations showed no changes which could have caused the normoblastosis. Fatty degeneration of the liver was regularly present, cirrhosis and regeneration of bile ducts were sometimes prominent features. No extramedullary blood formation was found.

Taking into consideration Cabot's anemic cases, the conclusion is justified that peripheral normoblastosis occurs especially in those patients with heart failure who

TABLE 3

No	Age	Diagnosis	Normoblasts	Duration of life after first detection of normoblasts	Cyanosis	Dyspnea	Thrombi in heart	Infarcts in lungs
			<i>per cent</i>					
1	34	Mitral disease	5	13 days	+	++	+	+

9	63	Mitral disease	2	3 months	++	++	—	+

are either markedly cyanotic or strongly anemic, so that it appears as if anoxia is the most important cause of the normoblastosis. We are inclined, therefore, to regard the occurrence of normoblasts in the peripheral blood as an indication of an attempt on the part of the body to increase the number of circulating red cells as a result of the stimulus which anoxia exerts on the blood-forming apparatus. Apparently, normoblasts appear in the peripheral blood only when anoxia is extreme, in a degree that occurs only in the very severe forms of heart failure.

Decompensation alone does not seem to produce the phenomenon, it requires the presence of thrombi and/or infarcts in the lesser circulation. This is probably the reason why Walter, Blumgart and Volk³ did not find normoblasts in the blood in their cases of congestive heart failure, as they excluded all cases with complications from their study. They noted, however, that there was an increase in reticulocytes in the peripheral blood in heart failure, which disappeared when the condition improved.

The presence of normoblasts in the peripheral blood in heart failure thus seems to indicate that the condition is complicated by mural thrombosis in the heart or

pulmonary artery, or by pulmonary emboli, or a combination of these conditions. Hence, it is easily understood why peripheral normoblastosis is a sign of such poor prognosis.

In some, but not in all cases, the normoblastosis was accompanied by a leukocytosis and (or) the presence of young precursors of the myeloid group. Some cases showed not only a peripheral normoblastosis but a distinct leuko-erythroblastic blood picture. This was most pronounced in one of Frank and Hartmann's patients who had a total white count of 21,000 and not less than 70 per cent nucleated red cells.

SUMMARY

The authors recommend the search for normoblasts in the blood of patients with severe heart failure. When normoblasts are found, a marked interference with the oxygenation of the blood, either by pulmonary infarcts or thrombi inside the heart, is most likely to be present. It seems justifiable to consider the prognosis as very grave in these cases. This rule proved to hold even in those cases where, concomitant with an improvement in the heart failure, the normoblasts disappeared temporarily from the peripheral blood.

THIAMIN DEFICIENCY IN THE RHESUS MONKEY

CLINICAL, METABOLIC AND HEMATOLOGIC OBSERVATIONS

Bj J F RINEHART, M D , L D GREENBERG, PH D , AND L L GINZTON, M D

AN IMPORTANT advance in nutritional research was the development of an essentially synthetic diet adequate for study of single deficiencies in the monkey.¹ It seemed most timely to restudy the vitamin deficiencies in a primate whose metabolic processes might be expected to approximate those of man most closely. This report is concerned with the study of thiamin deficiency. Seven rhesus monkeys (*Macaca mulatta*) were subjected to one or more episodes of thiamin deficiency. Observations were made on food consumption, weight, clinical behavior, thiamin metabolism and the blood picture. Finally the animals were sacrificed and detailed pathologic examinations were made. In this report the experimental method is reported together with the clinical metabolic and hematologic observations enumerated above. The pathologic findings resulting from recurrent thiamin depletion with particular reference to characteristic degenerative changes occurring in the heart muscle and severe retrogressive changes in the nuclear structures of the central nervous system have been reported²⁻³ and will be detailed elsewhere.

EXPERIMENTAL METHOD

The diet used in these experiments was a modification of the M-3 diet of Waisman et al⁴ and consisted of powdered sucrose 73, vitamin test casein (General Biochemicals) 18, Hawk and Oser salt mixture 4, and corn oil 2. Sulfited liver extract equivalent to 100 grams of Wilson Laboratories L fraction prepared according to the method of Kline and co-workers⁵ was added to each 4 kilograms of diet. The diet was dried, granulated and following the addition of 1 per cent calcium stearate compressed into tablets weighing approximately 2 grams. * The basal diet was fed ad libitum. The diet in pellet form had the advantage of curtailing waste and facilitating the estimation of the daily food consumption. A vitamin tablet containing daily dosages similar to those of Waisman et al was fed each day. Each vitamin tablet contained the following: nicotinic acid, 5 mg, riboflavin, 1 mg, pyridoxine hydrochloride, 1 mg, calcium pantothenate, 3 mg, choline dihydrogen citrate, 100 mg, paraminobenzoic acid, 100 mg, inositol, 100 mg, and ascorbic acid, 25 mg, plus sufficient powdered sugar to make a tablet weighing 1.5 to 2 grams. The monkeys accepted these vitamin tablets willingly and consumed them eagerly. Control monkeys were also given 1 or 0.5 mg thiamin chloride daily. In addition the monkeys received by mouth 5 drops of vitamin A and D concentrate twice weekly and additional sulfited liver extract (equivalent to 2.5 Gm daily) twice or thrice weekly as a source of biotin and folic acid. Some animals also received 5 drops of mixed tocopherols (Napco) once a week.

During the course of these studies the weights and daily food consumption were followed carefully. Blood was taken by venipuncture at approximately weekly intervals for the determination of thiamin.

From the Department of Pathology, University of California Medical School, San Francisco, California.

The work has been aided by a Grant from the California Fruit Growers Exchange and the A. B. Miller Fund. We are indebted to David Klein of Wilson Laboratories for generous supplies of Liver Fraction L.

* We are grateful to Mr. S. J. Dean of the College of Pharmacy for his assistance in the preparation of these tablets.

levels and for hematological studies. At autopsy portions of several tissues were removed from each monkey and prepared for analysis of thiamin and riboflavin content. The methods used for the analysis of thiamin of blood and tissues have previously been described.⁶ The method for the estimation of riboflavin will be reported in another article. The animals were tuberculin tested by injection with old tuberculin in the eyelids. Positive reactors were rejected. The monkeys were then placed on the purified diet with complete supplementation for one to two weeks, and control tests were carried out so that each monkey could serve as his own control. The occasional animal who failed to adapt itself to the diet or failed to gain in weight during the control period was rejected. With the exception of one monkey all the animals used weighed between 1800 and 3600 grams. The one exception was an older animal weighing 7000 grams which had previously been used in some other studies. In all, 7 monkeys were employed in this study and were subjected to one or more periods of depletion.

FIG. 1. THIAMIN DEFICIENCY IN MONKEY NO. 3146
Graph of food consumption, blood thiamin, and weight

CLINICAL OBSERVATIONS

The clinical behavior of the animals was in most respects similar to that reported by Waisman and McCall.⁷ In general the monkeys ceased gaining after two weeks on the thiamin deficient diet. This was either followed by a plateau of the weight curve for several days or by loss of weight. The weight loss was usually associated with a decreased food consumption and marked lowering of the blood thiamin as is shown in figure 1 and 2, which are representative of the changes observed in monkeys on the thiamin deficient diet. As the deficiency progressed the animals continued to lose weight, became apathetic and inactive, and weakness was evident. Finally, if the depletion period were prolonged, the animals became ataxic. Some developed prosis and tremors. Retching was observed on several

occasions The monkey would make every attempt to prevent the escape of vomitus from his mouth by trapping it in his buccal pouches and would ultimately reswallow it Convulsive movements have been observed in one or more of the animals If thiamin were administered at this stage a dramatic response was observed in twenty-four to forty-eight hours The improvement in locomotion, alertness and appetite was striking On the other hand, if the period of thiamin deprivation were not interrupted at this stage it was but a matter of a few days until the monkey was unable to sit on its perch or even stand upon the floor of the cage without difficulty

FIG 2 THIAMIN DEFICIENCY IN MONKEY NO 3177
Graph of food consumption, blood thiamin, and weight

At times there appeared to be a paralysis of the hind legs The animal could climb or move in the cage only by the use of its forelegs Occasionally the onset of acute thiamin deficiency was so sudden that no manifestations were evident, aside from weight loss, mild anorexia and decreased activity, until the animal became ataxic, followed by a state of collapse Edema was observed in only one animal during the period of depletion However, following administration of thiamin to acutely deficient animals we have in several instances observed the appearance of edema The control animals continued to gain weight (although not as rapidly as animals we have had on our stock diet), and to remain strong and healthy during the course of the experiment We have maintained control animals on the complete diet

for a year or longer without any obvious alterations in their strength or vigor. One control animal was sacrificed and autopsied after having been on the diet for a period of six months and no pathologic changes were in evidence during either gross or microscopic examination of the tissues.

THIAMIN METABOLISM

Blood thiamin. During the period while the monkeys were on the complete diet including the thiamin supplement, the blood thiamin levels ranged from 5.5 to 10 micrograms per 100 ml of whole blood. This range of values is similar to that observed by us in healthy human beings. Following withdrawal of the thiamin, and simultaneously with the first fall in weight and food consumption, the blood thiamin usually dropped to values of 4 micrograms or less. Except for some minor fluctuations these values remained low. When sufficient thiamin was administered, this was reflected in the blood level by a significant rise. The alterations of the

TABLE 1—*Thiamin Requirement of Monkeys*

3rd-4th depletion	1.7	250	8	18.3
73	2.57	2500	91	27.5
Average				15.5

blood thiamin levels are charted in figures 1 and 2. The blood thiamin levels of control animals remained well above 5 mg per 100 ml during the course of the experiment.

Minimal thiamin requirement. A rough estimate of the minimum thiamin requirement of the monkey can be obtained by observing the time required to redeplete an acutely deficient animal following the administration of a small dose of the vitamin. Although there is a possibility that a portion of the vitamin may pass through the gastrointestinal tract unabsorbed (if administered by mouth), or that a portion may be eliminated in the urine if the dose is too large, for this calculation the assumption is made that the full dose is retained. If the total dose is divided by the product of the elapsed time in days and the weight in kilograms, one obtains a value for the minimum daily requirement per kilogram of body weight. Calculations of this type have been carried out on 4 individual monkeys and are summarized in table 1. In the case of Monkey No. 3192 which was carried through four depletion periods, three different observations on this same animal are recorded. The values recorded show considerable variation. However, the average

value obtained is 15.5 micrograms per kilograms per day and is in close agreement with the value reported by Waisman and McCall.⁴ It should be pointed out that this does not represent an intake adequate for normal metabolism.

Tissue thiamin Certain tissues were removed at the time of autopsy and subjected to thiamin and riboflavin analysis. In nearly all cases (with the exception of one) the deficient animals were sacrificed in the terminal stage of deficiency by the administration of chloroform. For purpose of comparison a control animal was sacrificed at the termination of the study. The latter was in excellent health after having been maintained on this purified diet for a period of six months. In table 2 we have summarized the results of our analyses. These data show that there is a marked lowering of the thiamin content of every tissue examined in the deficient animals.

In the case of riboflavin the heart, kidney and liver concentrations of the deficient animals were found to be slightly higher than those observed in the control

TABLE 2

animal. However, this is offset by the greater concentration of this vitamin in the skeletal muscle of the control animal.

Although it is difficult to compare tissue vitamin levels of one species of mammal with those of another species since the intake is known definitely to influence the concentration of the vitamins, we can point out that the control levels found in the monkey are similar in some respects to those found in the rat and in man. Figures⁶ obtained in our laboratory on the rat on a 20% per day level are of the same order for heart and muscle, but higher values for kidney and lower values for liver are found in the monkey. In general, rats with acute thiamin deficiency show lower figures for the tissues analyzed than those found in the monkey during the acute stage of deficiency. The control thiamin values for monkey's skeletal muscle and heart are not significantly different from those of humans who have died of accidental death. Liver and kidney of human origin have shown lower values than those found in monkeys. The tissue thiamin values recorded in the control monkey probably represent saturation values in as much as the animal had received daily thiamin in excess of its metabolic requirement.

HEMATOLOGIC OBSERVATIONS

It is generally considered that thiamin deficiency per se has little if any influence in hematopoiesis ^{7 8} Our data indicate a significant influence on erythropoiesis as is illustrated in figure 3. It will be seen that with depletion for thirty days there was a slight but definite reduction in the red blood cell count and hemoglobin. At forty days this was obscured presumably by dehydration. However, at this time the reticulocyte count had fallen to zero. On administration of small subcurative doses of thiamin there were definite reticulocyte responses. Interestingly this was accompanied by a fall in the red blood cell count and hemoglobin which was probably brought out by correction of dehydration. A second

FIG 3 BLOOD IN THIAMIN DEFICIENCY IN MONKEY No 3192

animal showed a progressive fall of the red blood cell count and hemoglobin beginning at thirty days and continuing to the termination of the experiment at fifty days. In this animal the red blood cell count fell from 4.7 million to 3.6 million and the hemoglobin fell from 13.4 grams to 8.75 grams. The reticulocyte count during the early phase of the experiment approximated 1 per cent falling to zero between thirty two and fifty days. The complete suppression of circulating reticulocytes is of particular interest and is unique in our experience, not occurring in other deficiencies of the vitamin B factors studied. The small bleedings for metabolic studies probably contributed very little to the anemia. Such anemias did not develop in control animals. The cases cited are typical of the 4 animals in which hematologic examinations were made. The conclusion seems justified that thiamin

deficiency in the rhesus monkey will cause anemia and that the mechanism is evidently due to suppression of reticulocyte formation *

SUMMARY

Seven rhesus monkeys were subjected to one or more episodes of acute thiamin depletion. It is clear that significant metabolic inadequacies preceded demonstrable structural changes. Diminished food consumption and weight loss were manifest about two weeks after thiamin was removed from the diet. When the deficiency was prolonged the animals became apathetic, inactive and progressively weaker. This was followed by ataxia and at times ptosis and tremors. Even in such advanced states of depletion, administration of thiamin produced dramatic improvement in locomotion, appetite and reactivity. The blood thiamin content of normal monkeys ranged from 5.5 to 10.7 per 100 ml of whole blood, values which are comparable to those of healthy human beings. Following withdrawal of thiamin the blood concentration fell to values of 4.7 or less. The tissue content of thiamin was correspondingly reduced in depleted animals. The minimum daily requirement for thiamin calculated on the basis of the time required to redeplete a deficient monkey following a small dose of thiamin was approximately 15.7 per kilogram body weight. Characteristic degenerative changes in the heart muscle and severe retrogressive changes in the nuclear structures of the central nervous system previously reported were noted. Based on careful hematologic studies in 4 animals it is concluded that thiamin is essential for normal erythropoiesis. Acute or chronic depletion results in anemia due to suppression of red blood cell formation as indicated by severe depression or absence of reticulocytes in the blood.

ACKNOWLEDGMENT

We are indebted to Miss Mariette Quigley for the blood counts, and to Miss Ruth Johnson for assistance in thiamin assays.

STUDIES ON HYPOPROTEINEMIA I HYPOPROTEINEMIA IN PATIENTS WITH GASTRIC CANCER, ITS PERSISTENCE AFTER OPERATION IN THE PRESENCE OF BODY TISSUE REPLETION

By F HOMBURGER, M D , AND N F YOUNG, PH D

With the technical assistance of IRIS FORBES, A B

INTRODUCTION

HYPOPROTEINEMIA occurs with greater frequency in patients with gastric cancer than in patients with other neoplasms or with benign lesions of the gastro-intestinal tract. This was noted earlier by various authors,¹⁻⁶ and has been studied in this laboratory. Hypoproteinemia becomes more pronounced and resistant to therapy following surgical treatment for cancer of the stomach than following similar operations for benign lesions of the stomach or for cancers of other organs.

In previous studies from this laboratory, it was shown⁷ that the preoperative administration of large amounts of protein to patients with gastric cancer renders the postoperative hypoproteinemia less pronounced. The present study revealed that hypoproteinemia, once it is established in patients with gastric cancer following operation, is persistent in spite of the administration of large amounts of protein adequate to result in significant increase of body tissue protein.

CASE MATERIAL AND METHODS

GENERAL PLAN OF STUDY

Patients who underwent partial gastrectomies for benign gastric ulcers and patients undergoing similar operations or exploratory laparotomies for cancer of the stomach were given high protein, high caloric feedings as soon as possible following surgery. Nitrogen balances were recorded for from 7 to 108 days and potassium, calcium, sodium and phosphorus balances were studied as well. At regular intervals, plasma volumes, plasma protein concentrations and electrophoretic plasma protein fractions were determined. It was thus possible to evaluate nitrogen retention, body tissue repletion and plasma protein regeneration, to compare the changes occurring in patients with benign gastric lesions to those observed in patients with gastric cancer and to evaluate the utilization and distribution of nitrogen in both groups.

CASE MATERIAL

(Detailed case histories are given in the Appendix.) The initial plasma protein values of all patients are recorded in table 1.

Patients with Gastric Cancer

Three patients had cancer of the stomach which was operable, and underwent partial gastrectomy (cases 4, 5, and 6). These were 1 female and 2 males, aged 60, 46, and 50 respectively.

Seven patients had inoperable cancer of the stomach. Six of these underwent exploratory laparotomy.

From the Laboratory of Clinical Investigation, the Sloan-Kettering Institute for Cancer Research, New York.

This study was aided by grants from the Teagle Foundation and the National Cancer Institute.

* Length of study, days

† Beginning of study, days after operation

‡ Nitrogen balance for 10 days only, plasma protein change in 14 days

(cases 7, 8, 9, 10, 11 and 13) These were two females and four males, aged 69, 47, 52, 49, 70, and 64, respectively

One patient (case 12) was found to have a resectable cancer of the stomach which was removed, but firm, large lymph nodes were felt in the portal region and in the omentum and were not removed. This man was 65 years old.

Control Subjects

Three patients with benign gastric ulcers were studied (cases 1, 2, and 3). These were three males, aged 51, 45, and 53. This control group was kept small because previous work by Co Tui et al.⁸ had clearly shown that patients with gastrectomy for ulcers on a high nitrogen intake regenerate plasma protein within two weeks following operation and our findings confirmed this observation.

TABLE 2—*Routine for Administration of Protein Hydrolysate in Patients Following Gastrectomies as it Was Used at the Memorial Hospital at the Time of this Study*

Fifth day	60	q 2	45 cc q 2 hrs, 50 cc boiled milk added	After hydrolysate	1000

Sixth and seventh day as above. Reduce parenteral fluid according to patient's ability to swallow small amounts of water by mouth. Remove stomach tube on eighth day and start patient on routine seventh day gastrectomy diet.

Methods

1. *Alimentation* Some of the patients had orojejunal feeding tubes inserted at operation and left in situ for as long as seven days postoperatively. Some had external jejunostomy tubes for feeding purposes. Unless otherwise specified, casein hydrolysate Squibb* was used as a source of nitrogen in all cases. In general, the plan included the administration of 0.6 Gm of nitrogen per day per Kg of body weight in a mixture of the hydrolysate in a 10 per cent dextrose solution with 60 Gm of Amphojel. This feeding mixture was administered by the jejunal tube and/or by mouth and the total daily volume was adjusted to 720 ml. A feeding schedule given in table 2 was followed as closely as possible. After the first post-operative period this regimen was supplemented by the usual gastrectomy hospital diet in amounts measured in the metabolic kitchen and analyzed in the laboratory for nitrogen content. The caloric content of the total diet, including parenteral alimentation, was maintained at a level of approximately 1800 calories per day (except on the first, and sometimes, the second postoperative day when it was lower).

* The hydrolysate was provided by the courtesy of the Squibb Co.

Plasma and blood transfusions were given in all cases on the day of operation and thereafter as sparingly as possible to avoid interference with the observations on protein regeneration. Parenteral fluid intake was standardized as closely as possible, 1000 ml of physiologic saline solution and 300 ml of dextrose in water on the second and only rarely on the third postoperative day. All parenteral intake, as well as other alimentation, was carefully measured and recorded. The patients received a daily intramuscular injection of a vitamin B complex preparation* throughout the duration of the metabolic study. Other medication was given as indicated. The patients usually were allowed up on the second or third postoperative day, but this was not standardized. The 2 patients on whom long-term metabolic studies were carried out for 26 and 108 days were placed on a constant basic diet which was the same every day.

In addition, to maintain the desired high nitrogen content, these patients received part of their nitrogen intake in the form of protein hydrolysate (Casein Hydrolysate, Squibb) and in the form of native protein (milk protein as Delcos, Sharp and Dohme, and Lactalbumin Squibb in unhydrolyzed form).

2. *Collection of specimens* Urines were collected in 24-hour specimens, preserved at pH 3 with acetic acid, and kept in the refrigerator without preservative. Vomitus and gastric aspiration fluid were collected in 24-hour samples and kept in the refrigerator without preservative.

3. *Methods of Analysis*

Urine Urinary nitrogen was measured by a micro-Kjeldahl method. Potassium and sodium were measured by flame photometry⁹, phosphorus was determined by Fiske and Subbarow's method,¹⁰ and calcium by the method of Schohl and Pedley.¹¹ Creatinine determinations¹² were used to evaluate the accuracy of the collections.

Stools A commercial homogenizer was used for the thorough mixing of stools which were then made up to a standard volume by the addition of distilled water. Nitrogen was measured by a micro-Kjeldahl method, and minerals were determined in dry ashed aliquots by the same methods used in the urine.

Blood Plasma protein was measured by a micro-Kjeldahl method and corrected for nonprotein nitrogen. The plasma protein components were estimated by electrophoresis by Dr. M. L. Petermann.¹³ Plasma volumes were measured by the use of Evans blue.¹⁴

RESULTS

Body Tissue Repletion Table 1

Repletion within one month after operation In only 2 of the 3 ulcer cases studied were nitrogen balance studies done. The third case is included because, while nitrogen output was not measured, the nitrogen intake was known and was at least as high as in the two others. As previously shown by Co Tui et al.⁸ and by Reigel,¹⁵ positive nitrogen balance† was obtained in both cases, the usual postoperative nitrogen loss, therefore, was offset by adequate nitrogen utilization. This was achieved on intakes of 0.26 and 0.49 Gm of nitrogen per Kg per day, or considerably less than had been planned originally. All patients with gastric cancer were in nitrogen balance or had positive nitrogen balance 7 to 20 days following operation. There was essentially no difference between those having undergone exploratory laparotomy and the one case with gastric resection in which nitrogen balance studies had been done (case 4). The least marked nitrogen retention actually occurred in the latter case. The nitrogen intake in the cases with cancer ranged from 0.2 Gm per Kg per day to 0.81 Gm per Kg per day, with an average of 0.43 Gm per Kg

* Beta Symplex was used (Winthrop) which has the following composition: thiamin, 10 mg; riboflavin, 5 mg; calcium pantothenate, 5 mg; niacinamide, 50 mg.

† A patient is considered to be in nitrogen balance when the loss of nitrogen exceeds the intake by less than 0.01 Gm per Kg per day.

per day. An average of 26 per cent of the ingested nitrogen was retained as compared to 12 per cent (31 and -6 per cent) in the ulcer group.

Repletion more than one month after operation. Studies of nitrogen and mineral balances were made in 2 cases of gastric cancer following exploratory laparotomy (case 12) and following palliative gastrectomy (case 13) during periods of 26 and 108 days and starting 12 and 11 days after operation. These showed marked nitrogen retention 402 Gm. or 0.065 Gm. per Kg. per day for 108 days, equal to 13 per cent of the intake, and, 264 Gm. or 0.15 Gm. per Kg. per day or 34 per cent of the intake.

* Theoretic Nitrogen Intake means the amounts of nitrogen required for correction of the plasma albumin deficit (Assumed normal albumin 4.6 Gm./100 ml. All calculations are based on values obtained by the Howe method because this method was the one used in evaluating the proportion of albumin to the remaining body protein, ref. Elman, R. Protein deficiency in surgical patients and its correction. *J. Am. Diet. A.* 18: 141-144, 1942. The total calculated nitrogen requirement includes 4 Gm. for daily maintenance during the period of study, the tissue protein loss calculated from the albumin lost and assumes a loss of 50 per cent of the ingested nitrogen (above the maintenance requirement of 4 Gm. per day).)

† The calculated change of plasma protein is based on the amounts of nitrogen retained or lost, assuming that plasma protein represents one thirtieth of the total body protein.

in 26 days. There was concomitant retention of phosphorus and potassium in the proportions in which these minerals are known to exist in protoplasm. In these two instances, the ability of these patients to build body tissue is thus well demonstrated.

Plasma Protein Regeneration Table 3

Regeneration within one month after operation. In all patients with gastrectomy for benign ulcers, an increase in circulating plasma protein occurred promptly. The extent of this increase varied widely in these 3 patients and was predominantly in

the globulin fraction in one. The increase of the circulating plasma protein was of the same order of magnitude as that observed by Co Tui under similar conditions and not to be ascribed to changes of plasma volume alone (table 1). In all patients with gastric cancer except two (case 10 and case 7), there was a decrease of circulating plasma protein during the period of study. In case 10, the increase observed follows a rise of the plasma volume more marked than in most of the other cases and thus may be only illusory. In case 7, there was an actual increase, entirely caused by a rise of plasma globulin.

* Only total protein was determined

† Refers to total circulating fractions

Regeneration more than one month after operation. The changes of circulating plasma protein in these two cases following 26 and 108 days of postoperative high protein feeding were insignificant and probably within the range of technical errors.

Comparison of Theoretic and Actual Plasma Protein Increases Table 4

Studies by Weech¹⁶ in dogs showed that the plasma albumin represents $\frac{1}{10}$ of the body protein and by transferring this assumption to man, one can estimate the amounts of circulating albumin which theoretically should be formed from a given amount of retained food protein. Applying these relationships, Elman¹⁷ has devised a calculation to evaluate the nitrogen need of a depleted individual from his plasma albumin concentration. The further assumption may be made that albumin represents most of the plasma proteins lost in protein depletion and that thus, the total protein may be substituted for albumin in such cases. These rough theoretic figures demonstrate that on the whole the discrepancy between the actual and the

calculated figures is much wider in the group of cancer patients than in the two ulcer cases and that it becomes extreme in the long-term studies

DISCUSSION

Hypoproteinemia continues in gastric cancer patients after operation in spite of adequate body tissue repletion

Causes of hypoproteinemia are (1) inadequate formation, (2) increased utilization or destruction, or (3) abnormal distribution of circulating proteins. Inadequate formation may be due to (a) insufficient protein intake, (b) excessive nitrogen loss, or (c) specific defect in serum protein synthesis. In patients with gastric cancer who show hypoproteinemia before operation, insufficient intake and excessive loss of nitrogen have been eliminated by earlier studies.^{4, 5} The present investigation supplies evidence that inadequate intake and excessive loss of protein are not responsible for the persistence of the hypoproteinemia in gastric cancer patients after operation.

One concludes that either inadequate fabrication or distribution is responsible for hypoproteinemia in gastric cancer. The defect is probably nonspecific, as similar observations have been made in patients with tuberculosis.¹⁸ It may be related to the gastro-intestinal tract, to the liver, or to the adrenal cortex.

Further studies are in progress to determine if the hypoproteinemia is due to decreased synthesis, to increased utilization or destruction, or to abnormal distribution of proteins.

APPENDIX

Summaries of Clinical Histories of the Patients Studied

CASE 1

(B J 81337-11) colored male of 59 years. Admitted 6-25-46, discharged 7-9-46

History Anorexia for 2 years. Pain in midepigastrium for 2 months before admission. 13 lbs weight loss in 2 years. No vomiting, no tarry stools.

Physical examination Tenderness in epigastrium on deep pressure, no other findings.

X ray examination Gastric ulcer, lesser curvature.

*Laboratory data** Hemoglobin 82%, RBC 4,800,000 WBC 6,100, normal differential count. Urine negative. Serum chlorides 95-105 meq/l. Serum bilirubin 1.0-1.4 mg/100 ml. Blood urea nitrogen 12.2-30.4 mg/100 ml.

Gastric analysis† Free HCl 0, 0, 22, 24, 15

Total HCl 12, 18, 35, 36, 30

Operation Partial gastrectomy 6-24-46

Pathology Chronic peptic ulcer

Course Uneventful postoperative recovery. Discharged 15 days postoperatively, asymptomatic since

CASE 2

(M P 81622-42) white male of 45 years. Admitted 5-19-46, discharged 6-5-46

History Preprandial pain 7 years ago, successfully treated by dietary measures. Recurrence one year ago, unrelieved by diet. In the 4 months before admission, frequent vomiting. Only 4-5 lbs weight loss

* Data included in the paper are not repeated in the appendix

† First samples before 0.5 mg of histamine, following samples every 15 minutes thereafter. Acid in ml of N/10 NaOH

Physical examination Negative

X-ray examination Duodenal ulcer

Laboratory data Hemoglobin 89-103%, RBC 4,100,000-4,600,000 WBC 4,000-8,300, normal differential count Urine negative Serum chlorides 94-102 meq /l Serum bilirubin 1.1 mg /100 ml Fasting blood sugar 89 mg /100 ml Blood urea nitrogen 16.3-26.4 mg /100 ml

Gastric analysis Free HCl 25, 40, 60, 55, 50

Total HCl 44, 48, 64, 66, 60

Operation Partial gastrectomy, 5-22-46

Pathology Gastric ulcer, scars in duodenum, fibrous adhesions

Course Uneventful recovery Asymptomatic in April 1947

CASE 3

(F H 82072-17) white male of 53 years Admitted 6-25-46, discharged 7-17-46

History From 18 months to 1 year before admission pain after eating Weight loss in that period 25 lbs Vomiting for about 4 weeks

Physical examination Negative

X-ray examination Crater of $\frac{3}{4}$ inches in lesser curvature, probably benign ulcer

Laboratory data Hemoglobin 81%, RBC 3,700,000-4,500,000 WBC 5,000-15,000 Urine negative Serum chlorides 96-102 meq /l Serum bilirubin 0.7-1.3 mg /100 ml Fasting blood sugar 87 mg /100 ml Blood urea nitrogen 11.9-20 mg /100 ml

Gastric analysis Free HCl 55, 32, 28, 31, 35

Total HCl 28, 50, 65, 78, 58

Operation Partial gastrectomy, 7-2-46

Pathology Chronic peptic ulcer (gastric)

Course Patchy pulmonary infiltration on eighth postoperative day with moderate elevation of temperature Responded well to penicillin Asymptomatic since then

CASE 4

(K H 82018-34) white female of 60 years Admitted 6-27-46, discharged 7-19-46

History Abdominal pain of 2 months duration and weight loss of 20 lbs in 4 months before admission

Physical examination B P 160/85, soft systolic aortic murmur Rales throughout chest, emphysematous thorax Mass and tenderness in left upper quadrant Difficult examination because of failure to relax abdominal wall

X-ray examination Advanced gastric carcinoma of the body of the stomach and the pyloric region

Laboratory data Hemoglobin 63-88%, RBC 3,800,000-4,200,000 WBC 4,400-16,800 Urine negative Serum chlorides 93-106 meq /l Serum bilirubin 0.6-1.2 mg /100 ml

Gastric analysis Free HCl = 0

Total HCl 5, 4, 4, 6, 6

Operation Subtotal gastrectomy (4/5), Hoffmeister anastomosis 7-1-46 No liver metastasis or peritoneal implants found

Pathology Diffuse gelatinous adenocarcinoma, extension to the fat about nodes Lymph nodes proper were clear

Course Uneventful recovery Patient has left town, no follow-up recorded

CASE 5

(S S 82300-55) white male of 46 years Admitted 7-15-46, discharged 8-24-46 Readmitted for closure of colostomy 9-30-46, discharged 10-14-46

History 3 months persistent epigastric pain following fall from horse Lost 60 lbs in 4 months and noticed progressive weakness

Physical examination Essentially negative

X-ray examination No gastro intestinal examination

Laboratory data Hemoglobin 64-91% RBC normal WBC 9,000-15,000 normal differential count

Urine negative, except for occasional 1+ albumin Serum chlorides, 97-103 meq/l Serum bilirubin 0.6-4.8 mg/100 ml Serum cholesterol total 141, free 52, esters 89 mg/100 ml Fasting blood sugar 99 mg/100 ml Blood urea nitrogen 11.3-25 mg/100 ml

Gastric analysis Free HCl = 0

Total HCl 26, 10, 7, 10, 15

Operation No metastasis seen in liver, lymph nodes or peritoneum. A large tumor involving the greater gastric curvature and extending into the transverse colon and the omentum was found. Subtotal gastrectomy and resection of the medial portion of the transverse colon and a large portion of the omentum was performed. A Mikulicz colostomy was done (7-19-46). On 8-8-46, patient developed acute intestinal obstruction and a number of fibrous adhesions were dissected at an emergency laparotomy. The patient recovered and was discharged. On 10-4-46, colostomy was closed.

Pathology Adenocarcinoma, Grade III, invading entire thickness of gastric wall and extending into serosa of colon.

Course Patient now in good health.

CASE 6

(M. S. 82126-53), white male of 50 years. Admitted 6-30-46, discharged 7-22-46.

History Midpigastic pain for 7 months, with 11 lbs weight loss.

Physical examination Negative.

X-ray examination Carcinoma of lesser curvature, near cardia.

Laboratory data Hemoglobin, 48-87%, RBC 2,300,000-3,000,000 WBC 3,700-9,600, normal differential count. Urine negative. Serum chlorides 98-108 meq/l. Blood urea nitrogen 12.1-36.8 mg/100 ml.

Gastric analysis Free HCl 10, 25, 30, 55, 60

Total HCl 20, 40, 38, 75, 80

Operation No metastasis seen in liver, lymph nodes or peritoneum. Subtotal gastrectomy.

Pathology Adenocarcinoma of stomach.

Course Uneventful recovery.

CASE 7

(B. J. 80928-8), white male of 69 years. Admitted 3-21-46, discharged 4-8-46.

History Weight loss of 6 lbs in 3 months and loss of appetite.

Physical examination Negative.

X-ray examination Large mass in pars media of stomach.

Laboratory data Hemoglobin 75-85%, RBC 3,700,000-4,600,000 WBC 6,100-10,200. Normal differential count. Urine negative. Serum chlorides 100-108 meq/l. Serum bilirubin 0.7 mg/100 ml. Serum cholesterol total 197 free 61, esters 136 mg/100 ml. Fasting blood sugar 88 mg/100 ml. Blood urea nitrogen 12.4-13.2 mg/100 ml.

Gastric analysis Free HCl 0, 0, qns,* qns, 0

Total HCl 24, 7, qns, qns, 8

* Insufficient quantity.

Operation Laparotomy 3-28-46. A large mass was found involving the stomach, extending along both curvatures. Numerous metastatic nodules in liver, gall bladder, and nodes along aorta. Inoperable case.

Pathology Metastatic adenocarcinoma.

Course Complicated by hypoproteinemia (hypochloremia and edema). Patient was discharged, no follow-up notes.

CASE 8

(G. Y. 80364-96), white male of 47 years. Admitted 1-27-46, discharged 2-17-46.

History Past history of glycosuria. Negative urine at time of admission. Weight loss of 60 lbs in 18 months. Epigastric fullness and anorexia for 12 months.

Physical examination Evidence of weight loss, large abdominal mass

X-ray examination Large mass in region of cardia and larger curvature

Laboratory data Hemoglobin 58-95%, RBC 3,000,000-4,600,000 WBC 5,000-9,400 Normal urine
Serum chlorides 101-105 meq /l Serum bilirubin 0.5-0.8 mg /100 ml Serum cholesterol total 121-250,
free 42-71, esters 79-179 mg /100 ml Blood urea nitrogen 12.0-28.4 mg /100 ml

Gastric analysis Free HCl = 0

Total HCl 20, 10, 12, 8, 10

Operation Laparotomy 2-5-46 Large tumor mass, involving gastric cardia and greater portion of duodenum, as well as mesentery, spleen, pancreas, and lymph nodes Inoperable External jejunostomy

Pathology No biopsy material taken

Course Patient died 3-26-46 No necropsy

CASE 9

(B L 80901-6) white female of 52 years Admitted 3-19-46, discharged 4-9-46

History Dull abdominal pain for 4 months, small weight loss

Physical examination Negative

X-ray examination Polypoid infiltrating cancer of distal segment of stomach

Laboratory data Hemoglobin 65-82%, RBC 3,200,000-3,500,000 WBC 7,200-7,600 normal differential count Urine 4+ sugar, acetone 1+ (probably after glucose infusion All subsequent urines negative) Serum chlorides 91-103 meq /l Serum bilirubin 0.7 mg /100 ml Fasting blood sugar 91-100 mg /100 ml Blood urea nitrogen 8.5-20 mg /100 ml No gastric analysis reported

Operation Laparotomy and external jejunostomy 3-26-46 Large mass involving stomach, extension into lesser and greater omenta, multiple metastases in liver (biopsy material taken)

Pathology Metastatic adenocarcinoma

Course No follow-up notes

CASE 10

(S S 81726-51) white male of 49 years Admitted 5-28-46, discharged 6-26-46

History Weakness of 3 months duration and postprandial epigastric pain and tarry stools of 1-month duration No evidence of weight loss

Physical examination Abdominal mass 8 cm in diameter

X-ray examination Carcinoma of antrum of stomach

Laboratory data Hemoglobin 51-81%, RBC 2,500,000-3,800,000 WBC 5,300-14,000, normal differential count Urine negative Serum chlorides 95-104 meq /l Serum bilirubin 0.6 mg /100 ml Serum cholesterol total 141, free 52, esters 89 mg /100 ml

Gastric analysis Free HCl = 0

Total HCl 15, 8, 10, 12, 12

Operation Laparotomy and exclusion gastroenterostomy, 6-7-46 Large tumor of gastric antrum adherent to pancreas, and meso-sigmoid and colic vessels Numerous metastases in liver Firm lymph nodes

Pathology None reported

Course No follow up notes

CASE 11

(G G 82040-21) white female of 70 years Admitted 6-23-46, discharged 7-20-46

History Nocturia due to cystocele Marked weight loss (70 lbs) in 5 months before admission Anorexia and heart burn for one year prior to admission Negative gastro-intestinal x-ray examination some months before admission

Physical examination Mass of 10 cm diameter in mid abdomen

X-ray examination Gastric carcinoma

Laboratory data Hemoglobin 61-94% RBC 3,700,000-4,400,000 WBC 5,500-11,500 normal differential count Urine essentially negative Serum chlorides 90-102 meq /l Serum bilirubin 0.5-0.6 mg /100 ml Blood urea nitrogen 12.8-36 mg /100 ml

Gastric analysis Free HCl = 0

Total HCl 20 10 qns, 12 16

Operation Laparotomy, 6-28-46 Extensive carcinoma with metastasis to nodes and liver

Pathology Adenocarcinoma, Grade III

Course Convalescence complicated by bronchial pneumonia

CASE 12

(K R 83598-116) white male of 65 years Admitted 11-10-46, discharged 6-2-47

History Weight loss during one year preceding operation of about 30 lbs Several bouts of dark black stools and rectal bleeding

Physical examination Negative

X-ray examination Filling defect involving almost the entire pyloric portion

Laboratory data Hemoglobin 8.4-5.4%, RBC 1,190,000-5,000,000 WBC 4,700-8,800, normal differential count Urines negative Serum chlorides 92-104 meq/l Serum bilirubin 0.62 mg/100 ml Thymol turbidity 1.85 ml Cephalin flocculation 24 hours, negative Hippuric acid excretion 1.5 Gm Bromsulfalein retained in blood, 30 minutes, 2%, 45 minutes, 2% Serum cholesterol total 104, free 36, esters 68 mg/100 ml Blood urea nitrogen 16.3-22 mg/100 ml

Gastric analysis Free HCl = 0

Total HCl 20, 22, 28, 50, 34

Operation On 11-25-46, a large bulky lesion was found in the greater curvature of the stomach, a few nodes were palpated in the gastro-hepatic ligament The tumor was removed, and a gastro-jejunostomy was done Liver and peritoneum free of metastases

Pathology Gelatinous adenocarcinoma, Grade III, extensive lymphatic permeation, metastases to nodes

Course Essentially uneventful postoperative course This study was continued up to the 205th postoperative day ^{19a b} The patient died of carcinomatosis 66 weeks after operation Reviews of additional articles bearing on this subject, which have appeared since this paper was submitted, are noted in the references ^{19a b}

CASE 13

(S J 109237-4) white male of 64 years Admitted 8-28-46, discharged 10-14-46

History Weight loss of 40 lbs in 4 months before admission Hematemesis one month before admission, epigastric fullness

Physical examination Mass in epigastrium

X-ray examination Polypoid carcinoma of stomach (fundus and body)

Laboratory data Hemoglobin 46-76%, RBC 2,200,000-3,400,000, Hematocrit 18-37% WBC 4,500-10,600, normal differential count Normal urine Serum chlorides 108 meq/l Serum bilirubin 1.2 mg/100 ml Fasting blood sugar 107 mg/100 ml Blood urea nitrogen 15.9 mg/100 ml

Gastric analysis Free HCl = 0

Total HCl qns, 14, 14, 12, 10

Operation 9-9-46 Large tumor from cardia through antrum along lesser curvature Liver studded with metastases Exploratory laparotomy, biopsy from liver metastases

Pathology Gelatinous adenocarcinoma

Course Died Dec 1946

SUMMARY AND CONCLUSIONS

1 The existence of hypoproteinemia in patients with gastric cancer has once again been observed

2 The intractability of this type of hypoproteinemia in the postoperative phase to treatment with high protein diets and in the presence of positive nitrogen balance has been demonstrated

3 Long-term studies in two patients, for 28 and 108 days respectively, suggest that the persistence of hypoproteinemia in patients with gastric cancer in positive

nitrogen balance is probably not due to a marked degree of depletion of tissue protein stores alone. These patients retained more protein than would have been necessary to replenish depleted tissues.

4 It seems more likely that while such patients are capable of tissue protein synthesis, they fail to shift new protein into the blood stream.

ACKNOWLEDGMENT

STUDIES OF PHOSPHORUS METABOLISM IN MAN II A STUDY OF THE PERMEABILITY OF THE HUMAN ERYTHROCYTE TO INORGANIC PHOSPHATE IN VITRO BY THE USE OF RADIOACTIVE PHOSPHATE (P^{32})

By F H L TAYLOR, PH D, S M LEVENSON, M D, AND M A ADAMS, B A

With the technical assistance of MARY KENDRICK, B S

IT IS A distinct pleasure to dedicate the first published* of a series of articles from this laboratory on the use of radio isotopes in human physiologic studies to Dr George R Minot. It was under his direction that our venture into this field was undertaken.

Radio phosphorus has been used in the examination of various phases of phosphorus metabolism and the results have been summarized by Hevesy^{1, 2} and Kamen.³ Most of the data presented in the literature were obtained in animals, and by use of dosages of isotopic P^{32} in excess of what may be considered tracer amounts. Human studies on the metabolism of P^{32} in tracer amounts are few in number, most of the interest of previous authors having been directed to the therapeutic uses of the isotope. Since normal metabolic processes may be deranged by larger than tracer doses of P^{32} , it seemed of value to investigate the metabolism of phosphorus in the human body using P^{32} as a tracer in doses low enough to cause no demonstrable metabolic disturbance. These studies will be presented elsewhere.⁴ The use of P^{32} in such concentrations immediately imposes problems of revisions of methods and further considerations of accuracy of counting technics. These will be described fully in another communication.⁵

The first consideration in the attack on phosphorus metabolism was the resolution of the controversy of phosphorus exchange between cells and plasma of the circulating blood. The present communication is concerned with the distribution of phosphorus between red cells and plasma in in vitro studies of the phosphorus exchange between these two media. Eisenmann et al.,⁶ have shown in an in vitro system to which inorganic phosphate together with P^{32} were added to human whole blood, that at 38 C phosphate entered the red cells freely, while at 7 C the exchange was minimal. In their experiments 5 to 101 mg phosphorus were added to 100 ml of whole blood. They also stated that, under their experimental conditions, radio phosphorus accumulated in the cells out of proportion to the amount of inorganic phosphate present. Their observations were made on whole blood and plasma and the cell concentrations of phosphorus compounds were calculated using hematocrits.

In the present communication no phosphate was added except that represented by the P^{32} , which was negligible, since the specific activity of the isotopic sodium

* No. 1 of this series⁴ is in preparation.

phosphate used was very high. The *in vitro* studies presented in this paper have been extended to similar studies *in vivo* in man which will be presented elsewhere.⁴

METHODS

Blood from normal human subjects was collected in bottles containing dried potassium-ammonium oxalate solution which was prepared by dissolving 3 Gm of ammonium oxalate and 2 Gm of potassium oxalate by dissolving in distilled water to a volume of 100 ml. For each ml of blood, 0.04 ml of the anticoagulant was used. Such an oxalate mixture caused no change in cell size. P^{32} in the form of sodium phosphate solution was added to the whole blood, the volumes of the radioactive phosphate solution varying from 0.58 to 2.08 ml per 100 ml of whole blood, with activities of P^{32} varying between 900 and 12,000 counts per second as registered on our counter. Samples of the radioactive phosphate solution added were utilized as standards for each experiment, and were counted at intervals throughout the experiments to correct for the decay of P^{32} . Counting was performed with a Geiger-Mueller tube with fixed geometry, and the totalizing was accomplished by the use of an autoscaler.† The background count in this laboratory averaged 0.23 counts per second. In none of these experiments was there any count lower than ten times the background. In all experiments, samples were removed for the determination of the hematocrit about five minutes after the addition of P^{32} to the blood. In this same initial sample, chemical determinations of total, total acid soluble and inorganic phosphorus were made in both plasma and red blood corpuscles. In two of the experiments, the P^{32} content of the total phosphorus of plasma and cells was also measured in the initial blood sample.

The blood was then allowed to stand in contact with P^{32} , with frequent gentle shaking, for a period of four hours. In three cases this incubation took place at a temperature of 37.5°C, and in the fourth instance the blood was kept for four hours at 7°C. At the end of four hours, the hematocrit was again determined, total, total acid soluble and inorganic phosphorus were determined chemically in plasma and red blood cells, and the P^{32} concentration was measured in all these phosphate fractions.

Blood samples were centrifuged for ten minutes at 2000 rpm to separate the plasma from the red blood corpuscles. The plasma was drawn off as completely as possible, and the blood cells were washed once with cold 0.9 per cent sodium chloride solution. The washed cells were centrifuged, and the supernatant saline drawn off and discarded. The red blood corpuscles were then frozen at -20°C in order to produce hemolysis and to prevent any hydrolysis of organic phosphorus complexes. For analysis the frozen cells were thawed and diluted with the amount of distilled water required for each determination. The exact techniques employed are described elsewhere.⁵

The total phosphorus of both plasma and red blood cells was determined by the colorimetric molybdate method of Fiske and Subbarow⁷ preceded by digestion with sulfuric and nitric acids. Total acid soluble and inorganic phosphorus were determined by Fiske and Subbarow's method in trichloroacetic acid filtrates prepared from plasma and red blood corpuscles.

To determine the total amount of radioactive phosphorus present in plasma and cells, samples were simply dried and read with the Geiger-Mueller tube and autoscaler. The size of the samples was dependent on the amount of P^{32} originally added to the blood. The radioactivity of the total acid soluble fraction of both plasma and red blood corpuscles was measured in dried samples of the trichloroacetic acid filtrates.⁸ Inorganic phosphorus was determined by precipitation with calcium chloride as described by Fiske and Subbarow.⁸ The precipitated calcium phosphate was redissolved in acid, and samples taken from this solution were dried in order to measure the concentration of radioactive phosphorus in the inorganic phosphorus fraction. Certain corrections for geometry, film thickness, and protein volume, were made and applied to all estimations of P^{32} .⁸ It was estimated that the methods used were accurate to plus or minus 5 per cent to 10 per cent.

The results are expressed in one of several ways, either as the percentage of the amount of P^{32} added to the reaction flask, or as specific activities obtained by dividing the per cent of the added amount of P^{32} by the milligrams of the given phosphorus compound per 100 ml of plasma cells or whole bloods. The use of the percentage of added P^{32} rather than the number of counts as the basis of calculation permitted direct comparison of the different experiments despite variation in the actual amount of P^{32} added.

* P^{32} was supplied by Monsanto Chemical Company, Clinton Laboratories, Oak Ridge, Tennessee.
† Tracerlab, Boston, Massachusetts.

RESULTS

Distribution of Phosphorus Fractions between Plasma and Erythrocytes

The data are presented in table 1. It will be observed that the distribution between red blood cells and plasma on the initial, nonincubated, blood were in the range of those normally accepted. After four hours incubation at 37.5 C (experiments 1, 2, 3) there was no net exchange between cells and plasma of any of the phosphate compounds beyond experimental errors of the methods employed. There was a slight increase of the plasma content of all of the forms of phosphorus studied as incubation proceeded. The hematocrit increased slightly or remained unchanged during the experiment. Minimal hemolysis was present in all samples.

TABLE 1—*Distribution of Phosphorus Compounds between Plasma and Erythrocytes*

Exp No	Tissue	Temp	Initial (5 minutes)				After 4 hours incubation

* Hct—Hematocrit %

† Values given in mg per 100 ml of cells or plasma; figures in parentheses are values calculated for whole blood distribution from the hematocrit.

At 7 C, no change in hematocrit or distribution of phosphorus compounds occurred, nor was hemolysis of red blood cells observed.

There was no indication that inorganic phosphate of the red blood cells increased at the expense of the organic fraction during four hours of incubation at 37.5 C.

Acid soluble phosphorus in plasma was accounted for, within the limits of error, by the inorganic phosphorus both in the initial bloods and after the four hour incubation period at either 7 C or 37.5 C.

The data of table 1 include, in parentheses, a recalculation of the various phosphorus constituents as distributed in whole blood using the observed hematocrit and known dilutions of the blood as the basis of calculation.

When incubation was continued for twenty three hours at 37.5 C, a marked in-

crease of hematocrit was found and cell destruction, as indicated by marked hemolysis, was present. Concomitant with this cell destruction, marked increases in the plasma content of all the phosphorus fractions was found. For this reason data beyond an incubation period of four hours have been excluded from this communication.

Phosphate Exchange between Plasma and Erythrocyte

The data are presented in table 2. It may be seen that between 91 and 105 per cent of the added P^{32} was recovered, or determined, as present in the plasma and red cells. These figures represent the limits of accuracy of the methods employed.⁵

TABLE 2 — *Phosphate Exchange between Plasma and Erythrocytes**

* All values calculated on whole blood distribution data.

† C.P.S.—counts per second per 100 ml whole blood.

⁵ Figures in parentheses are specific activities calculated as $\frac{\% \text{ of added activity per } 100 \text{ ml}}{\text{mg of P compound per } 100 \text{ ml}}$

In two experiments the per cent of the added P^{32} in the total phosphorus and specific activities were determined for plasma and red cells five minutes after the addition of the P^{32} . At this time 3.6 and 6.7 per cent were found in the red blood cells.

After incubation at 37.5 C for four hours, about one third of the added radio phosphorus was detected in the plasma. In each instance in the plasma there had been no turnover between the inorganic phosphate and the residual acid soluble organic or other organic forms. When blood was kept at 7 C for four hours all of the added P^{32} also remained in the plasma in the inorganic fraction in which form it had been added.

At 37.5 C the exchange of phosphate between plasma and red blood cells was rapid, from 51 to 57 per cent of the added radioactivity being detected in the washed red cells at four hours.

Most of the P^{32} was in the inorganic fraction of the acid soluble phosphate. From 6 to 14 per cent of the added P^{32} was found in the organic fraction of the acid soluble phosphorus. There was no indication that in four hours there was any exchange to the nonacid soluble organic fractions. At 7 C. essentially all of the P^{32} was in the inorganic form.

From a study of the specific activities presented in table 2, it will be seen that the specific activities of the inorganic phosphate of the cells equals or exceeds that of the inorganic fraction in the plasma at the end of four hours.

The ratio of the P^{32} activity, in terms of percentage of the isotope added, between the red blood cell and plasma $\left(\frac{\text{per cent added } P^{32} \text{ in R B C}}{\text{per cent added } P^{32} \text{ in plasma}} \right)$ ranged between 1.4 and 1.7 with a mean of 1.5. In *in vivo* studies on five normal men five hours after injection of 100–200 microcuries of P^{32} this ratio was 6.4. In these instances the plasma level of P^{32} was rapidly falling for obvious physiologic reasons which were not duplicated in the *in vitro* experiments.

DISCUSSION

The data presented amply confirm the statement of Eisenmann and her co-workers⁶ that phosphate readily enters the red blood cells within a period of four hours at 37.5 C. The present investigations are free from any criticism that the entrance of the marked phosphate was due to the increased phosphate concentration of the plasma. Based, as they are, on direct determinations of P^{32} in both plasma and washed red cells, they show that the red blood cell is permeable to the phosphate ion. It is unfortunate that longer incubation studies were precluded by the physiologic changes in the red blood cell which culminated in its destruction by hemolysis. In the text it was indicated that incubation studies had been carried on beyond four hours at 37.5 C. Most of the data so obtained were vitiated by the hemolysis of the red cell. It is worth while mentioning that at twenty-three hours, the intracellular distribution of phosphorus compounds in the remaining cells did not differ markedly from those obtained at four hours. The slight increase in the plasma concentration of all the phosphorus derivatives is presumably due to slight hemolysis of the red blood cells.

The data indicate that while over 50 per cent of the added P^{32} entered the red blood cell at 37.5 C. in four hours, less than 15 per cent was found in the acid soluble organic fraction, the remainder having been present in the inorganic fraction. At this time the specific radioactivity of the red blood cell inorganic fraction was equal to or greater than the specific activity of the plasma inorganic fraction. Therefore, penetration and retention of phosphate in the red blood cell under these experimental conditions cannot be entirely accounted for by the formation of organic complexes.

It is well known that when whole blood is incubated at 37.5 C., the blood glucose rapidly falls, while when plasma or serum are so incubated the fall of glucose is very slow. It is possible that the transfer of phosphate from the inorganic to the organic acid soluble form may be due to phosphorylation which precedes the utilization of glucose by cells. This point is being further investigated.

Additional evidence that both the penetration of the red blood cell by phosphate and the turnover from inorganic to acid soluble organic phosphorus compounds may be functions of cell metabolism is given by a comparison of the data obtained at 37.5°C with that obtained at 7°C. In the latter case no significant exchange of labeled phosphate between red blood cells and plasma occurred and the small amount of P^{32} discovered in the red blood cell was confined entirely to the inorganic fraction.

This experience gives rise to the hope that *in vivo* studies of phosphate exchange in man can be undertaken using the red blood cell as a tissue cell model. If this is so, it will permit investigations of intermediate phosphate metabolism in man, where tissues such as the liver are not readily available.

SUMMARY

- 1 Phosphate exchange in red cells and plasma was studied *in vitro* using P^{32} in the form of sodium phosphate as a tracer.
- 2 No phosphate was added other than the isotopic preparation which was of high specific activity.
- 3 Inorganic phosphate exchanged freely between the plasma and the erythrocytes at 37.5°C in a period of four hours. Minimal transfer occurred at 7°C.
- 4 Most of the added P^{32} which passed into the erythrocytes during this time remained in the inorganic fraction, less than 15 per cent being found in the organic acid soluble fraction.
- 5 The specific activity of the inorganic phosphate of the erythrocytes was equal to or greater than that obtaining for the inorganic phosphate of the plasma at the end of the four hour incubation period at 37.5°C.
